Haemostasis by tube

SURGICEL NU-KNIT* Absorbable Haemostat is designed specifically for laparoscopy. Its double density gives extra strength and integrity so that after passing through a cannula it will unfold easily, ready for positioning on the bleeding site.

As well as providing express delivery, it acts faster at the bleeding site than traditional SURGICEL* Haemostat, saving valuable minutes of operating time. Also, left *in situ*, it offers reassurance of continuing haemostasis beyond the tamponade effect of surgery while it is absorbed over the following 7 to 14 days.

SURGICEL NU-KNIT*

ABSORBABLE HAEMOSTAT

first choice for atraumatic laparoscopic haemostasis

Product Licence PL5416/0005

SURGICEL NU-KNIT* Abbreviated Prescribing Information

Presentation Supplied as sterile pieces of creamy-white knitted textured fabric. **Uses** Adjunctively in surgical procedures to assist in the control of capillary, venous and small arterial bleeding.
Dosage and Administration Cut to size and apply directly to the bleeding surface with pressure. May be left in situ when it is absorbed within 7-14 days.
Contra-indications and Warnings Only the amount necessary to achieve haemostasis should be used. Remove any excess before surgical closure in order to facilitate absorption and minimise the possibility of fore body reactions. In urological procedures, minimal amounts of material should be used and care must be exercised to prevent plugging of the urethra, ureter or a catheter by dislodging portions of the product. Avo infected or contaminated wounds but if used the product must be removed prior to closure. Do not over-pack. Used in fractures or laminectomies, it must be removed as there may be interference with bone regenerat It should not be used on non-haemorrhagic serous oozing surfaces.It should not be used around the optic nerve and chiasma and must be removed from other neural pathways. Should not be impregnated with a infective agents or with other materials such as buffering or haemostatic substances. Absorption could be prevented in chemically cauterised areas. If used as a wrap during vascular surgery, do not apply too tigh Safety of use in pregnancy and lactation has not been established. However, the product has been in wide use for 30 years without any evidence of apparent hazard. There is no evidence that the product o breakdown products would have an effect on the foetus or on lactation.
Pharmaceutical Precautions Store under cool conditions, under 15°C. **Shelf Life** 5 years. **Legal Category** Not applicable.

Contents

Leading articles

1169 **Laparoscopic appendicectomy**
J. J. T. Tate
Laparoscopic appendicectomy has not become popular: the author explains why

1171 **Percutaneous transluminal angioplasty of the internal carotid artery**
C. L. McGuinness and K. G. Burnand
For atherosclerotic stenosis of the carotid artery this technique remains experimental

Reviews

1174 **Risk factors for squamous cell carcinoma of the oesophagus**
U. Ribeiro Jr, M. C. Posner, A. V. Safatle-Ribeiro and J. C. Reynolds
Cancer of the oesophagus has great diversity in geographical distribution, incidence and aetiology

1186 **Sepsis and fat metabolism**
J. S. Samra, L. K. M. Summers and K. N. Frayn
The catabolism of sepsis and the immune response may be altered by administering lipid emulsions

1197 **Laparoscopic inguinal hernia repair**
M. S. L. Liem and Th. J. M. V. van Vroonhoven
It is premature to advocate a transition from conventional to laparoscopic repair on a large scale

Original articles

1205 **Division of the sphincter of Oddi for treatment of dysfunction associated with recurrent pancreatitis**
J. Toouli, V. di Francesco, G. Saccone, J. Kollias, A. Schloithe and N. Shanks
Sphincter of Oddi stenosis causing pancreatitis is rare but responds well to sphincteroplasty with septectomy

1211 **Pancreatitis in childhood associated with villous adenoma of the ampulla of Vater** (case report)
M. Arif Mateen Khan, D. M. Thomas and E. R. Howard
Pancreatoduodenectomy was required

1212 **Technique of laparoscopic splenectomy with a powered vascular linear stapler**
W. F. A. Miles, J. D. Greig, R. G. Wilson and S. J. Nixon
Elective laparoscopic splenectomy is feasible but demanding

1215 **Changing management of pyogenic liver abscess**
R. Rintoul, M. G. O'Riordain, I. F. Laurenson, J. L. Crosbie, P. L. Allan and O. J. Garden
Percutaneous drainage and systemic antibiotic therapy successfully controls most abscesses, unless there is malignant bile duct obstruction

1219 **Recurrence of hepatocellular carcinoma after surgery**
J. Yamamoto, T. Kosuge, T. Takayama, K. Shimada, S. Yamasaki, H. Ozaki, N. Yamaguchi and M. Makuuchi
A large study which advocates wide anatomical resection to avoid recurrence of hepatocellular carcinoma in patients with cirrhosis

1223 **Randomized trial of periportal peritoneal bupivacaine for pain relief after laparoscopic cholecystectomy**
D. J. Alexander, S. S. Ngoi, L. Lee, J. So, K. Mak, S. Chan and P. M. Goh
Additional injection of bupivacaine into parietal peritoneum around port sites reduces postoperative pain

1226 **Cost–utility analysis of home parenteral nutrition**
D. M. Richards and M. H. Irving
Home care is approximately 65 per cent more cost-effective than hospital care

1230 **Randomized controlled trial of the effect of mannitol on renal reperfusion injury during aortic aneurysm surgery**
M. L. Nicholson, D. M. Baker, B. R. Hopkinson and P. W. Wenham
Mannitol reduces subclinical renal injury

1234 **Colour-coded duplex assessment alone before carotid endarterectomy**
J. Golledge, R. Wright, N. Pugh and I. F. Lane
Confirmation of a widespread view that routine angiography is not necessary

Original articles (continued)

1238 **Homocysteine: an independent risk factor for the failure of vascular intervention**
I. C. Currie, Y. G. Wilson, J. Scott, A. Day, D. Stansbie, R. N. Baird, P. M. Lamont and W. G. Tennant
It may be possible to identify and treat a subgroup with a poor prognosis for vascular intervention

1242 **Operative results of House advancement anoplasty**
S. M. Sentovich, P. M. Falk, M. A. Christensen, A. G. Thorson, G. J. Blatchford and R. M. Pitsch
Useful for all types of anal stenosis

1245 **p53 Mutations in primary colorectal adenocarcinomas and liver metastases** (short note)
J. Yao, H.-S. Goh and D. R. Smith
Further evidence that the p53 suppressor gene determines behaviour of colorectal tumours

1247 **Reduction of paraphimosis: a technique based on pathophysiology** (surgical workshop)
V. Raveenthiran
The glans is aspirated under penile block anaesthesia and after application of a proximal tourniquet

1248 **Role of the general surgeon in a British trauma centre**
I. M. Bain, R. M. Kirby, A. L. Cook, P. A. Oakley and J. Templeton
Specialist general surgical trauma surgeons do not yet seem justified

1252 **Randomized comparison of sitting and prone positions for stereotactic fine-needle aspiration breast biopsy**
T. H. Helbich, K. Dantendorfer, G. H. Mostbeck, S. Schick, P. Wunderbaldinger, M. Amering, R. Alexandrowicz and G. Wolf
Both are equally good with few vasovagal complications

1256 **Management of premenopausal women with primary breast cancer** (short note)
C. B. J. Woodman, J. Singleton, J. Coyne and A. Baildam
Some patients did not receive optimal treatment recommended in previously published guidelines

1258 **Altered lymphatic drainage after lymphadenectomy or radiotherapy of the axilla in patients with breast cancer** (short note)
C. I. Perre, C. A. Hoefnagel, B. B. R. Kroon, F. A. N. Zoetmulder and E. J. T. Rutgers
These treatments divert lymph flow to the contralateral axilla

1259 **Duplicated vermiform appendix** (case report)
K. T. Kjossev and J. E. Losanoff
A remarkable case in which the ectopic appendix at the splenic flexure of the colon was gangrenous

1260 **Prospective comparison of laparoscopy, ultrasonography and computed tomography in the staging of gastric cancer**
D. A. Stell, C. R. Carter, I. Stewart and J. R. Anderson
Laparoscopy has some advantages over imaging techniques

1263 **Functional and morphological study of the cricopharyngeal muscle in patients with Zenker's diverticulum**
G. Zaninotto, M. Costantini, C. Boccù, M. Anselmino, A. Parenti, D. Guidolin and E. Ancona
Physiological studies supporting incomplete relaxation of the cricopharyngeus muscle as an important factor in the aetiology of pharyngeal pouch

1268 **Anatomy of the extrinsic motor nerve supply to mobilized segments of the oesophagus disrupted by dissection during repair of oesophageal atresia with distal fistula**
M. R. Q. Davies
Could a less extensive mobilization reduce the incidence of dysmotility following repair of oesophageal atresia?

1271 **Small intestinal myoelectrical activity and bacterial flora after Roux-en-Y reconstruction**
E. Schippers, S. Willis, G. Ruckdeschel and V. Schumpelick
This experimental study suggests that prokinetic agents may be useful in the treatment of the Roux-en-Y syndrome

Original articles (continued)

1276 **Upper oesophageal sphincter function during general anaesthesia**
J. P. McGrath, C. McCaul, P. J. Byrne, T. N. Walsh and T. P. J. Hennessy
In 16 per cent of patients undergoing general anaesthesia, reflux of acid due to upper oesophageal sphincter failure occurs, irrespective of the use of muscle relaxants

1279 **Free revascularized jejunal loop repair following total pharyngolaryngectomy for carcinoma of the hypopharynx: report of 90 patients**
A. S. Jones, N. J. Roland, D. Husband, J. W. Hamilton and I. Gati
Five-year survival rate was 42 per cent, rising to 59 per cent, when used to salvage selected patients treated initially with radiotherapy

1284 **Laparoscopic surgery for gastro-oesophageal reflux: beyond the learning curve**
D. I. Watson, G. G. Jamieson, R. J. Baigrie, G. Mathew, P. G. Devitt, P. A. Game and R. Britten-Jones
Surgeons who have performed more than 20 procedures achieve improved results but there is still a small, but significant, reoperation rate compared with open surgery

1288 **Impaired gut barrier function in malnourished patients**
J. V. Reynolds, C. O'Farrelly, C. Feighery, P. Murchan, N. Leonard, G. Fulton, C. O'Morain, F. B. V. Keane and W. A. Tanner
Evidence of impaired mucosal tolerance in malnourished patients

Annual Course in Hepatobiliary and Pancreatic (HPB) Surgery

Incorporating an International Symposium on Liver Disease and Transplantation and the annual meeting of the Pancreatic Society of Great Britain and Ireland

18-22 November 1996

This five day course will cover recent advances in the management of patients with benign and malignant diseases of the liver, biliary tract and pancreas.

International guest speakers include:

Professor WC Meyers Professor TE Starzl

Topics will include: Acute and Chronic Pancreatitis, Pancreatic Cancer, Benign Biliary Diseases, Cholangiocarcinoma, Hepatocellular Dysfunction and Liver Support, Liver Trauma, Liver Transplantation.

Speakers include: Professor A Cavallari, Ms S Cheslyn-Curtis, Mr G Glazer, Mr NA Habib, Dr JE Jackson, Professor D Jaeck, Mr CD Johnson, Professor M Milicevic, Mr RW Motson, Dr J O'Grady, Professor E Papaevangelou, Dr M Pignatelli, Dr P Price, Mr JN Thompson, Dr D Westaby, Professor R Williams, Professor RCN Williamson.

Every day there will be short talks on: Topic of the day, Operation of the day

Course Organisers: Mr AK Kakkar, Mr N A Habib, Prof R C N Williamson

Course Fee: £410.00

Further Enquiries to: Wolfson Conference Centre, Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, London W12 0NN.

Cuschieri Courses in Minimal Access Therapy

SURGICAL SKILLS UNIT

Professor A Cuschieri : Director (MATTUS), Director of Surgical Skills Unit

The Surgical Skills Unit offers

- lab based skill courses
- simulated models on animal tissue
- experienced tutors
- live theatre demonstrations
- intensely practical programmes
- small group format
- MATTUS approved courses

Advanced Endoscopic Surgery- a 5 day lab based practical course for experienced endoscopic surgeons covering advanced skills such as endoscopic suturing techniques and internal and external knot tying. Endorsed by SAGES. Fee £1200.

Essentials of Laparoscopic Surgery - a 3 day lab based practical course covering the essential skills and safety procedures for basic laparoscopic operations. Recommended by E.A.E.S. Fee £550. (extended 5 day course also available).

Practical Aspects of Laparoscopic Fundoplication - a 3 day lab based practical course covering the practical and clinical aspects of both partial and total laparoscopic fundoplication. Fee £950.

Laparoscopic Colorectal Course - a 3 day lab based course for experienced laparoscopic surgeons aimed at giving the skills and confidence to develop clinically based colorectal laparoscopic surgery. Fee £900.

Endoscopic Surgery for Biliary Stones - a 3 day lab based course on single stage management of choledocholithiasis at the time of laparoscopic cholecystectomy. Covers skills of cannulation of CBD, choledochoscopy, stone extraction and suturing. Fee £850.

Endoscopic Thoracic Sympathectomy- a 2 day lab based course encompassing all aspects of Thoracic Sympathectomy. Aimed at the advanced minimal access surgeon.

Other Specialist Course are available in Surgical Skills Unit.

THE AUSTRALIAN AND NEW ZEALAND JOURNAL OF SURGERY

Chairman &
Editor in Chief
G. J. A. Clunie

ISSN 0004-8682
Published monthly

Editors
J. Ludbrook
I. B. Faris

The Australian and New Zealand Journal of Surgery, established for over 60 years, is the leading surgical journal published in Australia, New Zealand and the Asia-Pacific region. Published on behalf of the Royal Australasian College of Surgeons, the journal promotes outstanding surgical practice and research of contemporary and international interest.

High quality papers concerning all fields of surgery and its related disciplines are published. A programme of continuing education for surgeons at all levels is also provided as well as the occasional historical discussion. A comment and reply section encourages lively discussion on previously published articles. Comprehensive book reviews and a monthly meetings update also feature.

The Australian and New Zealand Journal of Surgery is indexed in *ADONIS, Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Info-Med, University Microfilms, CAB International, Scisearch, Current Clinical Cancer* and *Research Alert.*

The Australian and New Zealand Journal of Surgery is published monthly. The subscription rates for 1995 (Volume 65) Aus$276.00 (Australasia), US$392.00 and Aus$560.00 (elsewhere). The Journal is dispatched to subscribers outside Australasia by surface air-lifted post.

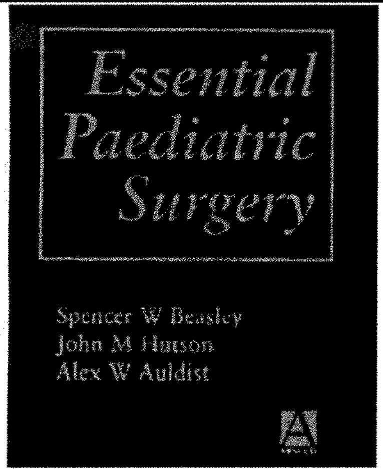
New from Arnold - *The Publisher of Choice........*

Essential Paediatric Surgery



Essential Paediatric Surgery is a highly practical guide for the General Surgeon having to treat children with surgical problems. The book covers all the common conditions which might be encountered and describes their operative management in detail, with emphasis placed on how to avoid common mistakes, and how to manage unexpected or unusual situations. In addition, it provides an update for General Surgeons who see infants and children with surgical (including neonatal) emergencies.

The book covers both elective and emergency situations, and gives clear guidelines as to when referral to specialist centre or specialist paediatric surgeon is required. It gives recommendations as to what type of treatment should be initiated immediately, and under which circumstances, particularly in neonates with major congenital abnormalities.

Authors:
Spencer W Beasley MB, ChB(Otago), Ms(Melb), FRACS
John M Hutson MD, Bs(Mon), MD(Melb), FRACS
Alex W Auldist MBBS(Melb), FRACS

Key Features

- ✓ ***Simple diagrams and photographs illustrate key points***
- ✓ ***Identifies potential problems and how to avoid them***
- ✓ ***Clear advice about when referral is required and what can be done safely by the General Surgeon***
- ✓ ***Clearly written in a straightforward style***

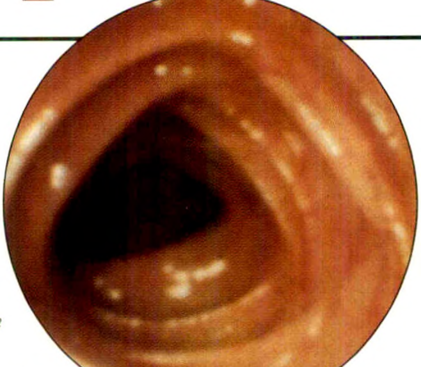
Trials show nothing comes cleaner[1,2] than Phospho-soda™



"Phospho-soda was graded as 'excellent' or 'good' in 86% of 21 cases for the quality of mechanical bowel preparation, compared with 63% of 19 cases for sodium picosulphate"[1]

"Overall, endoscopists scored sodium phosphate as 'excellent' or 'good' in 90% vs. 68% after the polyethylene glycol lavage."[2]

Fleet Phospho-soda gives you a thoroughly effective way to clean the colon before colonoscopy examination, radiological procedures or surgery.

Fleet Phospho-soda is an oral saline laxative, increasing fluid accumulation in the lumen by osmosis to give bowel movements in 1/2-6 hours.

Under clinical conditions, not only did Fleet Phospho-soda outperform sodium picosulphate in bowel cleansing, it was also associated with less abdominal pain in the patients taking it. In addition, with a total dosage of only 90ml, patients found it easier to complete the course when compared with other bowel cleansing preparations.

The trials tell the story again and again – when you require a really clean bowel for medical procedures, you want nothing less than Fleet Phospho-soda.

Fleet™
Phospho-soda™
Oral Solution For Bowel Cleansing

cribing Information:
ations: For use as a purgative for bowel cleansing in preparation for surgery or preparing the colon for x-ray or endoscopic examination. **Active Ingredients:** Each 45ml bottle (Dosage 2 x 45ml) ins the equivalent of 24.4g (54.3% w/v) Sodium Dihydrogen Phosphate Dihydrate Ph Eur and 10.8g (24.0% w/v) Disodium Phospate Dodecahydrate Ph Eur per 45ml. Sodium content is 5.0g per 45ml. ients: Glycerol, Sodium Saccharin, Sodium Benzoate (E211), Ginger-Lemon flavouring, Purified water. Fleet™ Phospho-soda™ is sugar-free. **Dosage: Adults only:** Unless directed by a physician, Fleet pho-soda should be taken in the morning and in the evening on the day before examination or surgery. **Note: No solid foods may be taken for breakfast, lunch or evening meal on the day of ng this medicine. The liquid "diet" indicated should be strictly adhered to.** ***1st Dose*** *– At 7 a.m. (morning) on the day before examination or surgery:* Dilute total contents of one bottle (45ml) in a glass (120ml) of cool water. Drink this solution, followed by one full glass (240ml) of cool water. At mid-day, follow with at least three full glasses (720ml) of water or "clear liquid", more if desired. "Clear ls" include water, clear soup, strained fruit juices without pulp, black tea or black coffee, clear carbonated and non-carbonated soft drinks. ***2nd Dose*** *– At 7 p.m. (evening) on the day before examination or ery:* Dilute total contents of the second bottle (45ml) in half a glass (120ml) of cool water. Drink this solution followed by one full glass (240ml) of cool water. Additional "clear liquid" may be taken up until ight if necessary. This product normally produces a bowel movement in 1/2 to 6 hours. **NOT TO BE GIVEN TO CHILDREN. DO NOT USE** when nausea, vomiting or abdominal pain is present, unless directed by hysician. **Contra Indications:** This product is contra indicated in patients with known or suspected gastrointestinal obstruction or ileus. Do not use in patients with congestive heart failure, hsprung's Disease or congenital megacolon. **Warnings:** Use with caution in patients with impaired renal function, heart disease, colostomy or on a low salt diet as hyperphosphataemia, hypocalcaemia, natraemic dehydration and acidosis may occur. Patients should be warned to expect frequent, liquid stools. **Interactions:** Use with caution in patients taking calcium channel blockers, diuretics, lithium ment or other medication that might affect electrolyte levels as hyperphosphataemia, hypocalcaemia, hypernatraemic dehydration and acidosis may occur. **Use in Pregnancy and Lactation:** Use under cal supervision only. **KEEP OUT OF REACH OF CHILDREN. Full prescribing information is available on request. Pharmaceutical Precautions:** Store below 25°C. Do not refrigerate. **Legal gory:** P. **Package Quantities:** Two single dose bottles, each containing 45ml of solution in a single carton. **Product Licence Number:** 0083/0044. **Product Licence Holder: E.C. De Witt & Co. Ltd., bsidiary of C.B. Fleet Company, Inc. U.S.A.** For further information please contact the Marketing Department at the address below. Fleet™ Phospho-soda™ (2 x 45ml) N.H.S. Price £4.79.

Laparoscopic appendicectomy

Laparoscopic appendicectomy was first described in the early 1980s but has never become popular. A recent audit on behalf of the Royal College of Surgeons of England suggested that only 1·2 per cent of patients undergoing appendicectomy had a laparoscopic operation[1]. Is laparoscopic appendicectomy dying from natural causes or neglect?

There are two possible advantages of the laparoscopic procedure over conventional open surgery: first, the diagnostic value of laparoscopy itself and, second, improved postoperative recovery. If one is convinced of the value of diagnostic laparoscopy, going on to remove an inflamed appendix thus found by a laparoscopic technique requires minimal additional effort. If one is not convinced, laparoscopic surgery must prove to offer significant advantages in its own right if it is to be attractive.

Diagnostic laparoscopy for suspected appendicitis is more accurate than clinical diagnosis. Potentially, two approaches might be adopted: to carry out laparoscopy on all patients admitted to hospital with acute abdominal pain, or to perform laparoscopy only when the clinical diagnosis of appendicitis has been made and the decision taken to operate. The former policy effectively replaces expectant management of lower abdominal pain. It allows earlier treatment of patients in whom the clinical diagnosis of appendicitis is not certain, but a high proportion of patients then subjected to laparoscopy will have a normal appendix and many of these could be managed expectantly. Diagnostic laparoscopy may 'save' many patients from having a normal appendix removed, but only at the cost of an invasive diagnostic test with its own morbidity[2]; this outweighs the benefit of earlier diagnosis. Other options, such as computer-aided diagnosis, ultrasonography or barium enema, may achieve improved diagnostic results more cheaply and with less morbidity[3]; the problem with these in most hospitals in the UK is lack of availability within a short timespan.

When a diagnosis of appendicitis is reached on clinical grounds and a decision made to operate, typically 20–30 per cent of patients are found to have a normal appendix. In adults, diagnostic laparoscopy reveals an alternative pathology in approximately half of these patients (10–15 per cent of the total); the remainder have no obvious pathology. Most, but certainly not all, of the patients with other pathology will be female. At open operation, however, it is also possible to detect pathology other than appendicitis, although the proportion is less than at laparoscopy. Thus, diagnostic laparoscopy has the ability to establish a diagnosis that would otherwise have been missed in up to one in 20 patients with suspected appendicitis. In many of these the management will be altered as a result. As over 40000 appendicectomies are carried out annually in England and Wales this may be important but, for an individual surgeon treating about 40 patients a year, the value of laparoscopy may appear unimpressive or non-existent.

Data assessing recovery after laparoscopic appendicectomy are available from several prospective randomized trials comparing open and laparoscopic surgery[4–8]. There is little difference between the operations in terms of postoperative pain. A shorter hospital stay after laparoscopic surgery is reported by some but not by all; this important outcome measure is difficult to assess as observer bias is possible, length of stay varies from one study to the next, and very short stays have been achieved after open surgery on which it would be hard to improve. Once at home, recovery may be faster after laparoscopic surgery and return to work earlier but, in truth, the differences are small and none of the studies is large enough to be convincing. A meta-analysis that is being undertaken by the University of Otago may provide a definitive answer.

A major difference between open and laparoscopic surgery is noted in wound complication rates, which are significantly reduced from up to 20 per cent after open surgery[9] to less than 5 per cent after laparoscopic surgery. All the available comparative studies[4–8] employed up-to-date antibiotic prophylaxis in all patients, and all reported fewer wound infections after laparoscopic surgery with a statistically significant difference in most reports. In addition, the wounds of laparoscopic appendicectomy are generally cosmetically better. Most surgeons claim they can remove an appendix through a very small incision but, with the exception of a small minority of the population, a given patient will have a smaller scar after laparoscopic than after open surgery, and the fatter the patient, the greater the difference. Smaller scars may not be the most important consideration but, all else being equal, they are preferred by the patient and may allow a faster recovery.

Laparoscopic appendicectomy probably costs more than the open operation, although some cost may be saved from reduced wound infection. Operating time is generally slightly longer than for open surgery, but this difference is of little practical or clinical significance, and the time improves with experience. Rates of conversion to open operation, typically between 10 and 20 per cent, are very low in some of the largest series, and there is no doubt that laparoscopic appendicectomy can be a demanding operation. Nevertheless, in no randomized study was the morbidity rate significantly greater than that of open surgery. It is also worthy of consideration that laparoscopic appendicectomy is an excellent procedure for training young surgeons and it may be a safer introduction to laparoscopic skills than laparoscopic cholecystectomy.

Appendicectomy is usually undertaken by trainees who do not have the experience or confidence in laparoscopy to use it routinely. It is an operation that is frequently done 'out of hours' when there are limited staff available who are, perhaps, unfamiliar with laparoscopic equipment; training may have to take second place to 'getting the job done'. The perception of surgeons who actually do the majority of appendicectomies appears to be that laparoscopic surgery is not worth the trouble and that they do not have sufficient experience of the technique. The diagnostic benefits of laparoscopy are small, as are the benefits of removing an inflamed appendix by laparoscopic means. Perhaps the combination of such benefits requires more careful consideration than it has so far been given, but the price of achieving this would be greater input from experienced surgeons into the teaching of the operation.

Percutaneous transluminal angioplasty of the internal carotid artery

The place of endarterectomy in both symptomatic and asymptomatic patients with varying degrees of internal carotid artery stenosis has now been established by several large clinical trials. No such trials evaluating the risks and benefits of percutaneous transluminal balloon angioplasty of the carotid vessel have yet been undertaken, although the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS), largely based at St George's Hospital in London and the Royal Northern Infirmary in Sheffield, is well underway.

Balloon angioplasty of the internal carotid artery was first performed in a patient with fibromuscular dysplasia and the technique was rapidly adopted for this condition[1]. The indications for carotid balloon angioplasty have now been extended to include atherosclerotic, vasculitic and radiation-induced stenosis. The procedure has, more recently, been used to dilate recurrent stenosis of the carotid vessels occurring after surgical endarterectomy or previous percutaneous transluminal angioplasty. These developments have been met with both enthusiasm and anxiety.

The potential benefits of percutaneous transluminal angioplasty of the carotid artery are avoidance of general anaesthesia, a short procedure time, a short hospital stay compared with that associated with carotid endarterectomy and, hopefully, a reduction in morbidity and mortality. However, almost all patients can be discharged 48 h after carotid endarterectomy and in one study the catheter technique required an average of 1·7 (range 1·5–2) h to perform[2].

The main concern about balloon angioplasty has been the risk of cerebral embolization, which is a recognized complication of carotid angiography. Monitoring by transcranial Doppler ultrasonography has demonstrated particulate embolization during carotid endarterectomy, carotid angiography and carotid balloon angioplasty. In one small study, embolization after percutaneous transluminal angioplasty was found to be common but usually symptomless[3]. Some authors have advocated that the catheter technique be combined with surgical exposure of the carotid artery in order to reduce the risks of blind arterial catheterization, while others have advocated the use of a balloon blocking system inserted into the distal internal carotid artery to trap any embolic material dislodged by the dilatation[4,5].

Problems of cerebral ischaemia may be anticipated in patients with a discontinuous circle of Willis because the carotid blood flow is completely obstructed during balloon inflation. A preliminary balloon occlusion test has been used to determine the effects of flow interruption. In one study this test alone caused three of 14 patients to develop a transient hemiparesis or sensory disturbance[2]. A shunt can always be inserted during surgical endarterectomy when there is evidence of cerebral ischaemia or poor middle cerebral blood flow; this option is obviously not possible during the percutaneous catheter procedure.

Reported complications of balloon angioplasty include failure to manipulate the guide-wire past the stenosis (in one series in 32 per cent of cases)[6] and arterial dissection following incorrect placement of the wire. Transient ischaemic attacks, transient strokes, completed strokes, haematoma formation, thrombosis, late ischaemic events and restenosis have all now been documented. One study[7] found that 51 per cent of awake patients experience cervical pain during the procedure. Another[2] reported transient bradycardia and hypotension during or after angioplasty in nine of 16 patients. In view of the anatomically widespread nature of atherosclerosis, it is surprising that there have not yet been any reports of false aneurysm or embolic complications affecting the distal limb after femoral or brachial catheter insertion; these are well recognized complications of coronary angiography and balloon angioplasty. There are also no reports to date of haemorrhage from the percutaneous insertion site.

Some authors have suggested that the results of balloon angioplasty for recurrent internal carotid artery stenosis following endarterectomy are disappointing. In one report[8], three patients had an attempted balloon angioplasty of surgical restenosis in the proximal internal carotid artery. One patient developed reversible spasm and transient stroke, while dissections developed in the other two. One of these dissections was further complicated by embolism and stroke, while the other was complicated by a transient ischaemic event that required operative thrombectomy and surgical bypass[8]. At present, it is impossible to arrive at any firm conclusion on the place of balloon angioplasty for recurrent carotid stenosis as most reports describe small numbers of patients followed for short periods. The potential use of stents adds yet another dimension. Their use in some circumstances may be advantageous but the late effects, including myointimal hyperplasia, need to be assessed. One study reported that two of six patients who had balloon angioplasty after surgical endarterectomy required reangioplasty at 6 months; a Palmaz stent (Johnson and Johnson, Bracknell, UK) was deemed necessary in one patient[8].

Several questions remain unanswered. Is the catheter technique safer to perform through a closed percutaneous femoral, brachial or carotid route, or using an open approach with distal carotid clamping? Should a percutaneously inserted balloon positioned in the distal internal carotid artery be inflated before dilatation of the narrowed segment? Is endarterectomy after a balloon angioplasty failure or restenosis more or less hazardous than endarterectomy after operative restenosis? Are some carotid plaques more dangerous to negotiate than others? Do certain characteristics of plaques render them less suitable for balloon dilatation?

Finally, little is known about long-term patency after balloon angioplasty of the carotid artery. Mean follow-up periods vary; a mean of 67 months was reported in one study[9]. Reported ranges also vary, from as little as 1 month to up to 7 years[10]. Yamamura *et al.*[2] have described significant restenosis in three of 16 patients followed for an average of 15·7 months. Markus *et al.*[3] reported significant restenosis in two of ten patients by 1 month.

Despite its potential advantages, percutaneous transluminal balloon angioplasty of the internal carotid artery remains an experimental procedure. Until the results of the CAVATAS become available, such treatment outside trial centres should probably be reserved for patients with particular indications, including surgically inaccessible lesions, significant concomitant medical conditions and fibromuscular dysplasia. The results should be audited carefully.

Editors' announcement

Illustrations in colour

The Journal does not contain many illustrations in colour at present, probably because authors are usually requested to make a contribution towards the cost of colour reproduction. This cost is substantial, amounting to approximately £500 per figure at current rates. In association with the publishers, Blackwell Science Ltd, The British Journal of Surgery Society is keen to increase the number of colour illustrations in the Journal. The use of colour is particularly appropriate for operative photographs (whether open operation or laparoscopy), resection specimens and especially photomicrographs. To encourage the submission of suitable illustrations in colour, authors' charges will be waived. Three high-quality prints of each figure should be submitted.

Review

Risk factors for squamous cell carcinoma of the oesophagus

U. RIBEIRO JR, M. C. POSNER, A. V. SAFATLE-RIBEIRO* and J. C. REYNOLDS*

*Departments of Surgery and *Gastroenterology, University of Pittsburg Medical Center, Pittsburgh, Pennsylvania, USA*
Correspondence to Dr J C Reynolds, Division of Gastroenterology and Hepatology, University of Pittsburgh Medical Center, Presbyterian University Hospital, 200 Lothrop Street, M Level, C Wing, Pittsburgh, Pennsylvania 15 213, USA

Cancer of the oesophagus has great diversity in geographical distribution and incidence. The rate of oesophageal cancer has been increasing in some areas and the reasons for this are not clear. This review outlines fascinating epidemiological aspects and the risk factors for squamous cell carcinoma of the oesophagus. While in the Western world the effects of alcohol and tobacco are substantial preconditions, worldwide other factors, such as diet, nutritional deficiencies, environmental exposure and infectious agents (especially papillomavirus and fungi), play a significant role. Chronic irritation of the oesophagus appears to participate in the process of carcinogenesis, particularly in patients with thermal and/or mechanical injury, achalasia, oesophageal diverticulum, chronic lye stricture, radiation therapy, injection sclerotherapy and gastric resection before the appearance of oesophageal tumour. The association of Plummer–Vinson syndrome, coeliac disease, tylosis and scleroderma with oesophageal cancer has also been reviewed.

Oesophageal cancer is the sixth most common cancer in the world and one of the most lethal tumours[1]. Squamous cell carcinoma (SCC) is the predominant histological type of oesophageal cancer worldwide, although in the USA and Europe the incidence of adenocarcinoma of the oesophagus and gastric cardia, including the oesophagogastric junction, has been increasing rapidly, especially among white men[2,3]. Advances have occurred in surgical technique, chemotherapy, radiation therapy and palliative measures, such as photodynamic therapy, laser therapy, and endoscopic stenting. Despite these innovations, there has been no discernible improvement in the prognosis of this disease which is associated with a 5-year survival rate of approximately 5 per cent. While no single cause of SCC has been identified, several factors are postulated to play a role in the development of SCC of the oesophagus and their effects may be additive or even synergistic. For several factors, there is a clear dose–response effect that persists even after adjustment for other possible risk factors. This review does not discuss adenocarcinoma and its association with Barrett's metaplasia, but instead focuses on risk factors for SCC.

Epidemiology

The wide geographic and cultural variation in incidence of SCC of the oesophagus suggests that environmental exposure is causally important[4,5] (*Table 1*). Regions with a high incidence of the disease are generally located in poor parts of the world whose inhabitants share several dietary characteristics[4,6]. They subsist on a diet high in starch and low in fresh fruit and vegetables, eat rapidly without sufficient mastication, and consume many foods and drinks at very high temperatures[6]. In the Western world, the incidence of SCC of the oesophagus varies among racial and socioeconomic groups[4,7–9]. Generally, lower socioeconomic groups have a higher risk[4,7–9]. In the USA blacks have a relative risk that is fourfold higher than that of whites[4,8]. Additionally, the incidence of cancer of the oesophagus is inversely related to level of education achieved[10].

Some geographic areas have an extremely high incidence, up to one per 1000 adults[4,11] A so-called 'Asian oesophageal cancer belt' stretches from eastern Turkey and east of the Caspian Sea through northern Iran, northern Afghanistan and southern areas of the former Soviet Union, such as Turkmenistan, Uzbekistan and Tajikistan, to northern China and India[4,5,11]. SCC of the oesophagus is also common among distinct populations in certain parts of Africa (the Transkei region of Cape Province and Kenya)[4,5,12] and among people with a regular intake of tea-rice gruel in a high-risk area of Japan[13]. Worldwide, men are more frequently affected than women, although the sex distribution shows considerable regional variation[4,11,14,15]. The causes of the higher male risk is unclear, but probably reflects sex-related

Paper accepted 29 February 1996

differences in diet, smoking and/or alcohol consumption. In the Asian oesophageal cancer belt, where environmental factors are thought to be aetiological, men and women are affected with equal frequency[4,5,6,15].

Histological precursors of squamous cell carcinoma of the oesophagus

Several lesions have been described in the malignant transformation of the oesophageal epithelium, including chronic oesophagitis, papilloma, atrophy, dysplasia and carcinoma *in situ*. The high prevalence of these lesions, even in the younger members of high-risk groups, the multifocality and the presence of concurrent cancer affecting the same sections of the oesophagus suggest that these lesions are associated[16,17]. Moreover, findings from follow-up studies have shown progression of chronic oesophagitis to more advanced lesions (atrophy, dysplasia and cancer) in the same regions that harbour oesophagitis[18]. Several endoscopic surveys performed in high-risk groups from different countries have demonstrated the presence of chronic oesophagitis in 42–84 per cent, atrophy in 3·8–10·8 per cent, and dysplasia in 2·4–8 per cent[16–18]. These results suggest that the natural history of oesophageal cancer may start with oesophagitis which, in a few individuals, progresses to atrophy and dysplasia of the epithelium and finally to neoplasia[18].

Aetiology

No single environmental factor can account for the pattern of oesophageal cancer in all high-incidence areas[4]. Risk factors that have been shown to be associated with oesophageal cancer are listed in *Table 2*. Oesophageal carcinogenesis is a complex multistep process, and certainly has a multifactorial aetiology. Some factors may be important in the initiation of the neoplastic state, whereas others may act in the promotion and progression of the lesion. Most certainly, the development of invasive oesophageal cancer will result from the synergistic actions between some or many of these aetiological factors. Correa[19] postulates that all the stages of oesophageal carcinogenesis require the action of three kinds of carcinogenic force: predisposing forces (vitamin deficiencies, such as those of A, B, C, E, riboflavin and niacin; oesophagitis, with small erosions and ulcerations), mutagens (nitroso compounds, tannin from cigarettes, alcoholic beverages, etc.), and promoters (phorbol esters present in some alcoholic beverages).

Alcohol and tobacco use

The role of tobacco and alcohol abuse in the aetiology of carcinoma of the oesophagus is well established[7–10,20–28]. Consumption of tobacco and alcohol has been shown repeatedly to be the major cause of SCC of the oesophagus. It has been estimated that more than 80 per cent of cases in industrialized countries can be attributed to exposure to these two environmental factors, either singly or jointly[4,14,20,21,25,28,29]. Large prospective cohort studies uniformly report an association between cigarette smoking and risk of SCC. Similar results have been

Table 3 Case-control studies showing the relative risks of alcohol abuse and tobacco smoke in oesophageal cancer

Reference	Year	Location of study	No. of patients with oesophageal cancer	No. of controls	Relative risk: Alcohol	Relative risk: Tobacco
Pottern *et al.*[8]	1981	Washington DC	120	250	6·4 (2·5–16·4)	1·9 (1·0–3·5)
Yu *et al.*[21]	1988	Los Angeles	275	275	15·5 (5·9–41·1)	11·5 (4·5–29·8)
Ferraroni *et al.*[10]	1989	Italy	209	1944	4·29	19·35
De Stefani *et al*[9]	1990	Uruguay	261	522	5·27 (2·7–10·2)	4·62 (1·9–11·1)
Graham *et al*[22]	1990	New York	178	174	3·07 (1·65–5·71)	2·49 (1·34–4·64)
Franceschi *et al.*[23]	1990	Italy	288	1272	6·0 (3·7–10·0)	3·8 (2·2–6·6)
Sankaranarayanan *et al.*[24]	1991	India	267	895	2·33 (1·52–3·55)	4·8 (2·34–9·83)
Cheng *et al*[26]	1992	Hong Kong	400	1598	11·45 (6·66–19·69)	5·83 (2·83–12·02)

Values in parentheses are 95 per cent confidence intervals obtained from well designed case–control studies (*Table 3*)[8–10,21–24,26]. Furthermore, such studies have shown a dose–response relationship after controlling for possible confounding factors[14,21,28,30].

The lighted cigarette generates about 4000 compounds that can be separated into gas and particulate phases. The major tumorigenic activity of tobacco smoke is contained in the particulate matter, or tar fraction. The primary initiators are presumably the polynuclear aromatic hydrocarbons, such as benzo(a)pyrene and volatile nitrosamines (*Table 4*)[4,9]. Pipe and cigar smokers have a greater risk of cancer of the oral cavity and oesophagus than cigarette smokers[9,20,23,27–29]. It has been proposed that pipe tobacco condensates are swallowed into the oesophagus, allowing close contact of the tobacco carcinogens with the oesophageal mucosa[27,28].

The relative risk of oesophageal cancer in smokers is higher in communities smoking mainly black (air-cured) tobacco than in those using blond (flue-cured) tobacco[9,27]. Black tobacco contains lower levels of polycyclic aromatic hydrocarbon and higher levels of *N*-nitroso compounds than blond tobacco[9,27]. These compounds have been proven to induce oesophageal cancer in rodents under experimental conditions[31]. Also, hand-rolled cigarette smoking, which could be considered an indicator of black tobacco smoking, was also associated with a higher risk of oesophageal cancer, compared with the use of commercial cigarettes[27]. The risk increases with increasing number of cigarettes and duration of the smoking habit[4,8,14,21,28,30,32]. Generally, ex-smokers of cigarettes have a reduced risk relative to those who continue to smoke, and current smokers of two or more packs per day display a higher risk than those who smoke less[4,9,21].

Differential risks for carcinoma of the oesophagus are also observed with different types of alcoholic drink[7 8 20 21]. For any given level of ethanol intake, the risk from spirits is usually more than twice that from beer; the risk from wine is intermediate between that from spirits and that from beer[7,8,20,21,32]. Whatever the type of alcohol consumption, however, there is a highly significant correlation with the average daily dose of ethanol[7,8,20,21,28,30]. The exact mechanism responsible for the increased risk in alcohol drinkers is not known (*Table 4*)[4,33,34].

Table 4 Carcinogenic actions of ethanol and smoking

- Ethanol
  - Direct local action by carcinogens (nitrosamines, oils, polycyclic hydrocarbons, etc.)
  - Interaction with other agents (tobacco)
  - Induction of nutritional deficiencies (riboflavin, nicotinic acid, iron, zinc, etc.)
  - Decreased chemical detoxification and biotransformation due to liver injury
  - Impairment of immune system
- Smoking
  - Direct local action by carcinogens (aromatic hydrocarbons, volute nitrosamines, etc.)
  - Exposure to heated smoke

The importance of either smoking or drinking alone as a single aetiological factor has been questioned, since so many patients who use tobacco also consume alcohol. However, several prospective case–control studies of patients who drink but do not smoke and, conversely, of patients who smoke but do not drink have established convincingly the independent importance of both tobacco and alcohol as carcinogens of the oesophagus (*Table 5*)[28,29,35]. In addition to their effect as independent risk factors, alcohol and tobacco exert a synergistic action by potentiating each other[8,14,28]. Data from a case–control study conducted in Ille-et-Villaine, a high-risk area of France, demonstrated that, while the relative risk for men consuming more than 120 g alcohol daily was 49·6 and the risk associated with smoking more than 30 g tobacco was 7·8, the risk for those who had both addictions was 155·6[36].

Dietary carcinogens

Epidemiological and experimental evidence suggests that nitrosamines are involved in the aetiology of oesophageal carcinoma[31,37]. A high content of nitrosamine in the diet is a particularly important risk factor in some African and Far East countries[6]. Nitrosamines and their precursors (nitrate, nitrite, and secondary amines) were detected in various common foods and drinking water consumed in Linxian County, China, an extremely high-risk area for oesophageal cancer. Moreover, residents of Linxian were found to have significantly higher urinary levels of nitrate and several *N*-nitrosamino acids[11,21,38]. Several studies in China have also shown an association between indices of exposure to *N*-nitroso compounds and death from oesophageal cancer[11]. Chronic oesophagitis is common in young people in Huixian where consumption of pickled vegetables during adolescence is associated with an increased risk of oesophageal cancer[11,26]. Pickled vegetables are known to contain high concentrations of *N*-nitroso compounds[26 39]. This finding strengthens the evidence that *N*-nitroso compounds are carcinogenic in humans and explains partly the very high risk of oesophageal cancer among other Chinese populations[26]. Nitrosamines contained in cured meat products and salted fish have also been considered as carcinogenic agents for oesophageal cancer[6,26,40]. A significant dose–response relationship between intake frequency of fried bacon or

Table 5 Case–control studies showing relative risk of alcohol abuse and tobacco smoke in non-smoking and non-drinking patients respectively

Reference	Year	Location of study	No. of patients with oesophageal cancer*	No. of controls*	Relative risk†	
					Alcohol	Tobacco
Tuyns[28]	1983	France	734	1976	11 04	5 16
La Vecchia and Negri[29]	1989	Italy	250	1089	3·6 (0·9–13·6)	6·2 (1·3–29·9)
Cheng *et al.*[15]	1995	Hong Kong	400	1598	3·18 (1·5–6·7)	10·27 (1·83–57·64)

Values in parentheses are 95 per cent confidence intervals ham and risk of oesophageal carcinoma has been observed[21].

The Kashmir province of India, another high-risk area, is associated with several specific personal and dietary habits[40]. The diet contains substantial amounts of *N*-nitroso compounds. These include salt tea, dried fish, vegetables (especially *Brassica olerecea*), red chillies and spice cake. The dietary habit that is likely to have the greatest risk for SCC of the oesophagus is the consumption of smoked fish and large quantities of hot, salted tea[40]. Drying raw foodstuffs in the open sun under humid conditions provokes high concentrations of *N*-nitroso compounds[40]. A high proportion of households in the high-risk region of Turkoman Sahara also preserve their food by local methods such as sun-drying and salting. Moreover, they tend to store these foods for longer periods than families in moderate- and low-risk regions[41]. A clear increase in risk has also been observed for those eating barbecued food daily compared with those eating it less frequently, even after adjusting for meat consumption[9]. Laboratory investigations showed the presence of animal carcinogens and mutagens in barbecued foods formed by the pyrolysis of proteins[9].

Nutritional deficiencies and dietary risks

Although epidemiological research has linked poor nutrition with cancer in large populations, such studies are inadequate for measuring the relationship between specific dietary deficiencies and risk of disease in relatively homogeneous populations[42]. Most evidence suggests that a chronic low intake of several micronutrients, together with an inadequate protein intake, increases the predisposition of the oesophageal epithelium to neoplastic transformation[33]. Diets deficient in vitamins A, C, E, niacin, riboflavin and zinc have been suggested as risk factors for oesophageal cancer[33,43,44]. Vitamin A and riboflavin deficiencies have long been known to promote hepatic and skin carcinogenesis in certain animal models, and to cause extensive lesions in the oesophageal epithelium of both animals and humans[33,43,44].

Food habits, such as a long-standing simple starchy diet without fresh fruit and vegetables, resulting in nutritional deficiencies, and continuous physical and thermal irritation of the oesophagus may play an important role in the aetiology of SCC[4,6,25,41]. Most studies have found an inverse relationship between fruit and vegetable consumption and risk of oesophageal cancer, although the evidence is less clear in some investigations. Attributing protection to any specific micronutrients is, at present, impossible; beta-carotene, vitamin C and riboflavin have been proposed as possible candidates[1,23,33,45]. Rural Transkeians at high risk of oesophageal cancer were found to have an inadequate intake of calcium, nicotinic acid, riboflavin and ascorbic acid[12].

Case–control studies carried out among black men with oesophageal cancer in Washington DC revealed that they ate more processed and starchy foods and less red meat, chicken, eggs, fruit and vegetables than controls[8,46]. In addition, several studies in Europe have shown significant negative associations between the consumption of fresh meat, vegetables and fruit, and risk of oesophageal cancer[4,23,25]. Zinc levels have been found to be lower in patients with oesophageal cancer than in healthy controls[11]. Experimentally, severe zinc deficiency increases the incidence of methylbenzylnitrosamine-induced oesophageal cancer in rats[47]. A deficiency of nicotinic acid is the outstanding nutritional feature of corn-eating populations[33]. Pellagra emerged as a common disease in Transkei around 1930, a high-risk area for oesophageal cancer[33] . Clinically, patients with pellagra usually have an intensely hyperaemic and sometimes oedematous oesophageal mucosa; others develop secondary ulcerations, constrictions, and dysphagia[33]. Signs of oesophagitis were also found in 80 per cent of individuals among the population of Iran at high risk for oesophageal cancer[16,33]. Foods that provide large amounts of retinol appear to increase the risk of cancer of the oesophagus substantially and in a dose-dependent fashion[22].

A comparison of incidence of oesophageal cancer with dietary staples and composition of foods in 21 low- and 17 high-risk regions in Africa revealed that in the low-risk regions, the dietary staples were either sorghum, millet, cassava, yams or peanuts, or a combination of these food items, whereas in the high-risk areas there was a starchy diet, consisting of corn or wheat, and nutritional deficiencies[6,33]. It is calculated that dietary staples associated with a high risk of oesophageal cancer are deficient in riboflavin, nicotinic acid, magnesium and zinc, whereas dietary staples associated with a low risk of oesophageal cancer are rich in these substances[33].

Environmental factors and pollutants

Environmental factors appear to play a predominant role in oesophageal carcinogenesis. As early as in 1966, Burrell and his associates[48] proposed the soil theory to explain the endemic spread of oesophageal cancer in Transkei, South Africa. Areas of high incidence of this neoplasia were distinguishable from those of low incidence by differences in either the plantation productivity on the ground or the content of molybdenum and other trace elements in the soil[11,48]. High-risk areas were much lower in both the biological and chemical richness of soil than low-risk areas[11,48,49]. The association of suboptimal geochemical environment with an increased cancer risk was also reported in Iran[50], China[51] and Japan[49]. Japan was divided into high-risk and low-risk regions. The ten highest-risk areas and the seven lowest-risk areas were clearly separated by two fault lines of the Japanese islands, a finding suggesting that some microelements of the soil may play a role in conditioning the cancer risk[49]. High-risk areas are either loam lands with a predominance of volcanic ash precipitate or raised sea bottoms covered with a layer of metamorphic rock. Low-risk areas, located along the Fossa Magna Line and the Median Line, are associated with an abundance of granite rock penetration from the rock magna. There is an inverse correlation between mortality rate from oesophageal cancer and soil content of molybdenum, manganese, zinc, magnesium, silicon, nickel, iron, bromium, iodine, chlorine, potassium, sodium, phosphorus and bicarbonate[11]. How these substances affect the oesophageal epithelium is not known but, for example, molybdenum is a co-factor of the enzyme nitrate reductase which affects the nitrite and nitrate content in plants[11,49].

An increased incidence of oesophageal cancer has been linked to petroleum contamination of water in Saudi Arabia[52]. Traces of petroleum oil were found in five of six water samples from Gassim, a high-risk area, compared with three of 49 samples from other areas. Mutagenicity tests on water specimens from Gassim region indicated the presence of possible carcinogens. Concurrent malnutrition, particularly vitamin A deficiency, may further enhance the carcinogenic risk of such pollutants[52].

Some authors have found a significant association between carcinoma of the oesophagus and long-term occupational exposure to metal dust (beryllium, chromium, chromates and nickel)[21]. These metals have been shown to be risk factors for respiratory cancers in humans, lending some credibility to the hypothesis that the observed association between oesophageal cancer and exposure to metal dust is a causal one. A possible occupational hazard in vulcanization workers, plumbers and pipefitters has also been identified[53].

Infective factors

Micro-organisms may also have an aetiological role in oesophageal carcinogenesis either by producing carcinogens or promoters, or by acting directly on host cells[54]. The chronic inflammatory processes caused by infectious micro-organisms may result in sustained regenerative proliferation of cells and increase the risk of cancer development[54]. The striking geographical distribution of oesophageal cancer might represent another example of a malignant tumour with a possible viral aetiology[55,56].

Human papillomaviruses (HPVs) of various DNA types have been strongly implicated in the pathogenesis of cancers that develop in several squamous epithelia, including cervix, vulva, larynx and skin[54–56]. In the past decade, HPV infection has also been found in chronic oesophageal irritation, papilloma and oesophageal cancer[54–62]. HPV infection of the oesophagus was suggested by morphological studies showing HPV-induced cytopathic changes, and confirmed by immunohistochemical techniques demonstrating HPV antigens in squamous cell papillomas[55,57,60]. Subsequently, DNA hybridization studies and polymerase chain reaction techniques disclosed HPV DNA sequences in both benign and malignant oesophageal lesions[58,60,62]. HPV is particularly prevalent in high-risk populations in China and in patients with cytological evidence of precancerous lesions. HPV was found in 22·0 per cent of patients without cytologic atypia, 50·0 per cent with mild dysplasia, 80·6 per cent with moderate dysplasia, 67·9 per cent with severe dysplasia and 66·7 per cent with invasive SCC[56]. Additionally, *in vitro* and *in vivo* experimental studies have confirmed the oncogenic properties of HPV types 16 and 18[62,63]. Protein of HPV types 16 and 18 E6 binds to the tumour-suppressor protein p53 and promotes its degradation[64].

Fungi have also been implicated as aetiological agents in oesophageal cancer[54]. In areas where oesophageal cancer is prevalent, grains and foodstuffs are frequently contaminated with fungi. Studies in the high-risk areas for oesophageal cancer in China showed that some common species of fungus, belonging to the genera *Fusarium*, *Alternaria*, *Geotrichum*, *Aspergillus*, *Cladosporium* and *Penicillium*, are frequently detected in grain[11,51,65,66]. Such fungi can not only reduce nitrates to nitrites but also decompose proteins and increase the amount of amines in food, consequently promoting the formation of nitrosamines. Maize grown in poor soil with zinc and molybdenum deficiencies has been identified in the high-risk areas for SCC of the oesophagus[67,68]. Molybdenum deficiency increases the susceptibility of maize to a variety of fungal species, especially *Fusarium* and *Aspergillus*, which are capable of producing carcinogenic metabolites[38,54]. Of the various infections of the oesophagus, fungal infections, particularly those of *Candida* species, are by far the most common[54,69]. The presence of fungus, as determined by cytological analysis, correlates with the degree of dysplasia. Oesophageal fungus was found in 31 per cent of normal subjects and those with mild dysplasia, in 72 per cent of those with severe dysplasia, and in 90 per cent of those with oesophageal cancer[11,54].

Bacteria are normally present in the upper alimentary tract, including the oesophagus. In the human oral cavity, nitrates are partially (20 per cent) converted into nitrites by the oral microflora[54,70]. Deregulation of the normal flora may increase the production of these compounds. Extremely high concentrations of nitrates and nitrites were detected in gastric juice and saliva in Linxian inhabitants[54]. Salivary nitrates in patients with marked epithelial dysplasia or oesophageal cancer were significantly higher than in normal controls[54].

Chronic oesophageal irritation

Thermal and mechanical irritation. Chronic chemical and/or physical irritation of the oesophageal mucosa is frequently reported by patients who develop oesophageal cancer. Ingestion of extremely hot beverages has been shown to increase the risk of oesophageal cancer in Puerto Rico[32], Singapore[71], Iran[72], Uruguay[9], Brazil[73], India[40], China[11,54] and Japan[13]. Opium smoking has been implicated in oesophageal cancer in high-risk areas of Iran and China[72], while ingestion of betel nuts is a frequent habit of inhabitants of Sri Lanka[74]. Several studies have observed an association between drinking of the plant extract mate and precancerous and SCC of the upper digestive tract[9,73,75]. The drinking of mate is a common habit in parts of southeastern South America where the gaucho culture is widespread, including Argentina, Uruguay, southern Brazil and Paraguay. These areas, particularly Uruguay and southern Brazil, have high incidences of oesophageal cancer[73]. Two possible mechanisms by which mate drinking might increase the risk of oesophageal cancer include a carcinogenic effect of the plant extract or an increased susceptibility of the oesophagus to carcinogens following thermal injury from hot mate[9].

Fibrous material contaminates the diet in north-east Iran where there is a very high incidence of oesophageal cancer[76]. Examination of the seeds from more than 60 different species of weed known to contaminate the wheat in this area of the Middle East shows that the fibre originates from the seeds of the common Mediterranean grass, *Phalaris minor*. The fibres are broken off from the seed when the wheat is milled but persist in the flour. Experimentally, when cells of the 3T3 mouse fibroblast line are exposed to these fibres in semisolid suspension culture, their proliferation is stimulated more than 100-fold[76].

Irritation of the oesophagus by curry or spicy seasonings has been considered as a possible risk factor in oesophageal cancer[6]. In the USA, a case–control study showed that 35 per cent of patients with oesophageal cancer preferred spicy foods, compared with 21 per cent of controls[20]. A study in Puerto Rico[32] showed that 3 per cent of the patients *versus* 1 per cent of the controls used a large quantity of spices. Part of the traditional diet during pregnancy in the high-risk region of northern Iran is black pepper, which may be related to the high incidence of cancer of the oesophagus among women in northern Iran[6].

Partially chewed food swallowed rapidly may cause continuous physical irritation to the oesophagus. Epidemiological studies have revealed that most patients with oesophageal cancer eat their food very quickly without chewing it well. This is particularly true in northern Iran, where the main food is local bread, which is often hard, scratchy and contains fibrous silica[6].

Achalasia. Achalasia is a motility disorder caused by degeneration of the intrinsic autonomic nerves in the wall of the oesophagus and lower oesophageal sphincter. This results in decreased or absent peristalsis in the smooth muscle portion of the oesophagus and impaired relaxation of the lower oesophageal sphincter[77]. Fagge[78] in 1872 was the first to report oesophageal cancer in patients with achalasia. Although it is generally agreed that oesophageal cancer occurs in those with long-standing achalasia, the true prevalence and incidence of malignant degeneration in achalasia is still a matter of debate[77–96]. Autopsy studies on patients with achalasia in whom oesophageal cancer was detected at post-mortem examination revealed a prevalence of 20–29 per cent[81,83,84]. The prevalence reported in clinical studies of patients with achalasia in whom oesophageal cancer was detected during a follow-up period ranged from 0 to 8·6 per cent (*Table 6*). The duration of follow-up, and both the number and selection of patients, influence the risk of malignant degeneration, which varies from seven-fold to 33-fold[88,92,94–96].

Symptoms of achalasia are present for an average of 15–20 years before the diagnosis of carcinoma is made[87–89]. The tumour usually develops in the dilated portion of the middle and lower thoracic oesophagus[88–90]. It frequently extends for some distance along the oesophagus, is often cauliflower in shape and has a marked tendency to invade by extension through the submucosa[86,90]. Most oesophageal cancer complicating achalasia is SCC, although adenocarcinoma associated with Barrett's oesophagus has been reported following surgical myotomy[77,97]. Reflux and subsequent oesophagitis are common late complications of surgical myotomy for achalasia, occurring in 18–31 per cent of patients[98]. Because of the high incidence of reflux oesophagitis after simple myotomy, many surgeons propose adding an antireflux procedure[98,99].

Carcinoma as a complication of achalasia is rarely found in its early stages because patients with long-standing difficulty in swallowing are likely to attribute any symptomatic change to their original disease[88]. Weight loss and an alteration or recurrence in the pattern of dysphagia are the most common harbingers of malignant change[86,87,89,91]. Blood-stained regurgitation or haematemesis, and retrosternal or back pain are other common symptoms of malignancy[87,90]. Radiographic and endoscopic recognition of the carcinoma can be difficult, because relatively large growths may arise from the wall of a dilated oesophagus filled with fluid and food and so escape detection[89,90]. Proper preparation of the oesophagus is, therefore, an essential part of these diagnostic procedures[88,89]. Because of the delay in diagnosis, the prognosis is extremely poor[88–91,93]. The extent and spread of the growth usually precludes the possibility of a curative procedure. The resectability rate is low, approximately 20 per cent for patients with achalasia and oesophageal cancer[92].

The mechanism responsible for the increased risk of SCC in patients with achalasia is unclear, but it is most likely related to stasis. Guisez[100] in 1921 called attention to the role played by stasis in the malignant transformation in achalasia. It is believed that development of the tumour is related to prolonged contact of certain elements of often partially degraded ingested food with the oesophageal mucosa; these result in increased bacterial growth and chemical irritation that culminates in chronic oesophagitis[88,93]. Endoscopy usually reveals a hyperaemic mucosa, irritation and spasm. Biopsy at this stage will demonstrate infiltration by inflammatory cells[86]. Thus, it is conceivable that early treatment to relieve retention may reduce the risk of oesophageal cancer; late operation on a dilated oesophagus does not prevent the development of cancer[87,89]. The incidence of tumour in patients with achalasia according to the treatment employed (no treatment, pneumatic dilatation, myotomy) has been studied. SCC occurs eight times more frequently in untreated patients with achalasia and 4·5 times more often in patients treated by pneumatic dilatation than in those having surgical myotomy[94].

According to studies of cell growth kinetics and data from mass screening programmes, progression from carcinoma *in situ* to invasive oesophageal SCC may take 3–4 years[92,101]. Therefore, an endoscopic surveillance programme may be indicated in those with achalasia,

especially when there is a history of dysphagia lasting 15 years or more[82,89,92,93]. Further studies are needed to clarify the cost-effectiveness of such surveillance.

Chronic lye strictures. Late complications of acid or lye burns in the oesophagus are cicatricial strictures and the development of carcinoma[5,102,103]. The magnitude of the risk is not definitely known. The incidence of lye corrosion in oesophageal cancer is generally between 0·8 and 5·0 per cent[103–106]. Kiviranta's[105] findings of nine patients with carcinoma in a group of 381 with caustic injuries suggests that the risk of oesophageal cancer is approximately 1000-fold greater than for others in the same age group[103,105,106]. The average age for development of SCC after caustic injury is about 50 years, compared with approximately 60 years for SCC of the oesophagus without previous exposure (*Table 7*)[103,104,106–108]. The time interval from the caustic burn to the onset of carcinoma averages about 40 years[103,104,106–108]. As with primary oesophageal cancer, men are more frequently affected than women[103–106]. The lye stricture is usually found in the area of the tracheal bifurcation and the carcinoma usually develops in the stricture[5,103,104,106–108]. The mechanism by which a caustic burn predisposes the patient to carcinoma is unclear. Experimental studies in rats have demonstrated that oesophageal tumours develop after *N*-ethyl-*N*-butylnitrosamine, most commonly in areas of oesophageal stenosis[109]. This may be equated to other situations of chronic inflammation, such as the increased risk of cancer in achalasia or chronic ulcerative colitis[106].

Appelqvist and Salmo[103] noted a better prognosis for lye corrosion carcinoma compared with ordinary oesophageal cancer. They suggested that patients with lye corrosion carcinoma are younger, obstructive symptoms occur sooner in an already narrowed oesophagus, and the lye stricture is surrounded by scar tissue which prevents early dissemination of the carcinoma[103,106]. Because of the high risk of development of SCC of the oesophagus, regular endoscopic examination including cytological study of endoscopic washings and biopsy should be done[104].

Oesophageal diverticuli. Malignant transformation in a chronic pharyngo-oesophageal or Zenker's diverticulum is rare and most of the reported cases appear in the literature as reports of single cases[110–114]. Of 961 surgical cases of pharyngo-oesophageal diverticula at the Mayo Clinic from 1930 to 1968, three were complicated by carcinoma, an incidence of 0·31 per cent. All patients were over 60 years old and all had had a large pharyngo-oesophageal diverticulum for many years[110,111]. Most authors have speculated that the chronic irritation and inflammation resulting from retained food and secretions in these large pouches are contributing factors in the development of carcinoma[110,111]. The diagnosis is often delayed, which may explain the low long-term survival rate[110]. Consequently, a diverticulum that is large enough to produce symptoms leading to its diagnosis is large enough to warrant operation[110–114].

Irradiation and chemotherapy. Therapeutic irradiation is well known to be associated with an increased risk of neoplasm development in organs within the irradiated field[115–123]. Experimental induction of SCC of the oesophagus in mice has been reported with an incidence related to the intensity of the radiation administered[119]. The number of reported cases of SCC of oesophagus following irradiation is anecdotal[115–118,120–122]. It is sometimes doubtful whether a carcinoma arising within a previously irradiated organ is due to radiation or whether it constitutes a second primary cancer unrelated to radiotherapy[117,118]. Criteria suggesting the diagnosis of radiation-induced malignancy are: (1) a previous history of irradiation; (2) appearance within the irradiated field; (3) observable chronic radiation damage; and (4) a long interval between exposure to radiation and development of the malignancy. The latter two criteria are not regarded as absolute[121,123].

The effects of radiation appear to differ according to age at the time of exposure, dose, duration of radiation and the tissue irradiated. Chemotherapeutic agents have also been known to cause certain tumours[120–124]. Systemic therapy may confound the radiation-induced cellular injury or interfere with cellular repair mechanisms. It is possible that the incidence of a second neoplasm represents a carcinogenic effect superimposed upon a susceptible patient.

The initial disease can be divided into benign and malignant conditions, including thyroid disease, tuberculous adenitis, breast cancer, lymphoma, laryngeal cancer, carcinoma of the testis and others[115,116,121,122]. The dose ranges from 26 to 100 (mean 46·8) Gy[115,117,120]. There is no obvious correlation between dose and latency[117]. The latent period between initial radiation therapy and diagnosis of oesophageal cancer ranges from 3 to 56 (mean 25) years and is significantly shorter in patients who received irradiation for malignant disease[117,118]. Women are more frequently affected than men and the predominant histological type is SCC; few cases of adenocarcinoma, fibrosarcoma and leiomyosarcoma have been reported[115–122]. Vigilant follow-up of patients with previous mediastinal irradiation is essential for early recognition and prompt treatment of subsequent SCC of the oesophagus[118,121].

Injection sclerotherapy. Endoscopic injection sclerotherapy has been widely used for treatment of bleeding oesophageal varices. Several isolated cases of oesophageal cancer following endoscopic sclerotherapy have been reported[125–127]. The middle and lower third of the oesophagus are the preferential sites for development of

Table 7 Clinical characteristics of patients who developed oesophageal cancer following caustic injury in reported series

Reference	Year	No. of patients	Mean age (years)	Interval since caustic injury (years)	Site of tumour			Resectability (%)
					Upper	Middle	Lower	
Bigelow[107]	1953	10	35	31·2	—	—	—	10
Imre and Kopp[108]	1972	10	52	40·5	2	6	2	50
Appelqvist and Salmo[103]	1980	63	48	41·5	5	53	5	83
Hopkins and Postlethwait[106]	1981	12	53	45·8	2	9	1	75
Isolauri and Markkula[104]	1989	15	57	52·5	0	14	1	67

tumours and the majority are SCC[125]. Prognosis is generally poor because of advanced carcinoma and accompanying liver dysfunction[125]. Some authors believe that the relationship between sclerotherapy and oesophageal carcinoma is fortuitous, emphasizing a causal association with other risk factors such as age, alcohol–tobacco intoxication, or Barrett's oesophagus[127].

Genetic predisposition

Although ethnicity is a strong indicator of risk for this disease, no specific genetic factor has been identified[5]. Because ethnic groups tend to share similarities in diet and geography, the identification of specific population-based genetic risk is difficult. There are several reports, however, that indicate an increased incidence among blood relatives[128,129]. The frequency of oesophageal cancer varies among the native and immigrant populations in different countries. A follow-up survey of 622 families with a history of oesophageal cancer was carried out in Yangcheng County, China, totalling 5037 families[130]. During a 10-year period, 35·8 per cent of new deaths were found in families that previously had two or more deaths due to oesophageal cancer, which accounted for only 7·8 per cent of the total families. Offspring from households where one or both parents died from oesophageal cancer also showed a higher mortality from the same disease[130]. These results point to a strong tendency of familial aggregation of oesophageal cancer and the existence of genetically determined susceptibility.

Second primary tumour

SCC of the oesophagus is also frequently associated with other synchronous or metachronous tumours in the upper aerodigestive tract[131–151]. The incidence of multiple primary SCC of the aerodigestive tract ranges from 3·7 to to 30 per cent[131–151]. Crude rates below 11 per cent have been reported in studies with a relatively short follow-up. This wide range in incidence may be explained partially by the site of the index tumour, type of treatment, ethnic and racial differences, increased life expectancy, and partially by the increasing awareness of such tumours, leading to more prompt evaluation and improved survival rates associated with the initial primary lesion[137,138,142,148]. These multiple neoplasms are highly selective on a site-specific basis, presumably because of common aetiological factors associated with the initial cancer.

The risk may be directly proportional to the amount and duration of exposure to carcinogens. Moore[149] found that 40 per cent of patients with index cancers of the oral cavity, pharynx and larynx, who continued to smoke developed a second primary tumour, while only 6 per cent who stopped smoking after onset of the first lesion did so. The time necessary to develop the second tumour is dependent on several factors, one of which is the survival time following treatment of the index tumour[148]. The risk of developing a second primary cancer is enhanced significantly by more intensive, combined exposure to tobacco and alcohol before identification of the index cancer[147,150]. When comparing former with current cigarette smokers, prospective studies have generally indicated a 25–50 per cent reduction in the risk of cancer of the oral cavity and larynx by cessation of smoking[147–150].

The field effect theory has been advanced to explain these so-called synchronous and metachronous carcinomas[131]. This model predicts that independent tumours will develop from the genotoxic effects of carcinogen shared by many cells in the field. The entire mucosa of the upper aerodigestive tract, when exposed to such local irritants as tobacco, smoke and alcohol, is at risk of developing cancer. According to this theory, areas of atypical epithelial hyperplasia, metaplasia, dysplasia, preinvasive carcinoma (*in situ*) and fully developed carcinoma may be found at various sites in the upper aerodigestive tract. The present authors studied 17 patients with multiple primary tumours of the upper aerodigestive tract for the presence and genotype of p53 gene mutations. The results showed a complete discordance in p53 genotype between separate primary tumours and, therefore, favour the field effect theory[151]. Because of the clear risk for metachronous cancers, it is recommended that all patients with tumours of the upper aerodigestive tract undergo close medical follow-up over a long period of time. This should allow early detection of second primary cancers, especially tobacco-related lesions[135,136,146].

Gastric surgery

There is some controversy regarding the increased relative risk of oesophageal cancer in patients who have undergone gastrectomy for benign conditions. Increased risk was reported from several cohort and case–control studies with large numbers of patients[152–155], but this has not been supported by other reports[156]. Gastrectomy may cause gastric hypoacidity and favour oesophageal reflux, leading to development of Barrett's oesophagus and adenocarcinoma of the oesophagus. An increased relative risk was observed for cancer of the colon and rectum, biliary tract, female breast, pancreas, oesophagus, bladder and lung 20 years or more after gastric surgery[152–155]. These findings suggested that the gastric stump may produce circulating carcinogens such as *N*-nitroso compounds, related to bacterial overgrowth. Some compounds in this class of chemicals are locally acting carcinogens, for example *N*-nitrosamides, while others, such as *N*-nitrosamines, require metabolic activation before the carcinogen is produced[153,154].

Associated diseases

Plummer–Vinson syndrome. Plummer–Vinson syndrome results from a complex deficiency of vitamins (lactoflavin and nicotinamide) and iron[157]. Patients present with atrophy of the oral, pharyngeal and oesophageal mucosa, hypochromatic anaemia and other symptoms. There is frequent occurrence of functional spasms of the oesophagus and cardia which can lead to dysphagia (sideropenic dysphagia). The patients are almost always women, usually between 15 and 50 years of age. They often give a history of weakness and anaemia of many years' duration. The lips are thin and the opening of the mouth is small and inelastic[5,157,158]. There is an increased predisposition to the development of carcinoma of the upper alimentary tract, especially in the mouth, upper part of the oesophagus and hypopharynx. Approximately 10 per cent of patients with this syndrome develop oesophageal or pharyngeal cancer[5,157,158].

Coeliac disease. Patients with either adult coeliac disease or idiopathic steatorrhoea are at increased risk for development of malignant lymphoma and gastrointestinal carcinoma, although the magnitude of this risk is not yet clear[159–162]. Malignancy develops more commonly in men than in women. Although some authors suggested initially that the risk of malignancy may be reduced by adherence to a gluten-free diet, further analysis is required to support this finding[160,161]. When oesophageal cancer develops, it is of squamous cell origin in all cases; two-thirds of lesions are identified in the middle and one-third in the lower oesophagus[161]. The mean age at the time of diagnosis of coeliac disease is 50 years. The interval from the onset of symptoms of coeliac disease to the development of malignancy varies from 15 to 30 years[159–162]. The basis of the association between coeliac disease and gastrointestinal carcinoma is unknown. The nutritional deficiencies that are frequently present in these individuals have been proposed as important factors.

Tylosis. This disease is a hereditary autosomal dominant dyskeratosis, which is characterized by severe epithelial thickening of the hollows of the hands and soles of the feet, and multiple oesophageal papillomas. It has a 95 per cent risk of development of oesophageal cancer after the sixth decade of life[5,163].

Scleroderma. Oesophageal involvement occurs in 70 per cent of patients with scleroderma[164,165]. Reports of several isolated cases of oesophageal cancer associated with scleroderma have raised the possibility of an increased risk of cancer in these patients. The duration of scleroderma before the diagnosis of oesophageal cancer is generally over 10 years and most of the carcinomas are of squamous cell type[166]. The reported prognosis is very poor, with an expected survival of less than 6 months after diagnosis[164,165]. Recently, cases of adenocarcinoma have also been described[167] . It has been speculated that such adenocarcinomas develop as a complication of a Barrett's epithelium. Gastro-oesophageal reflux and peptic oesophagitis may result from a weakened lower oesophageal sphincter and delayed gastric emptying[168].

Review

Sepsis and fat metabolism

J. S. SAMRA, L. K. M. SUMMERS and K. N. FRAYN

Oxford Lipid Metabolism Group, Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford OX2 6HE, UK
Correspondence to: Dr K. N. Frayn

Sepsis is a common surgical problem which can induce profound changes in the plasma concentrations of cytokines and hormones, leading to a catabolic state. Hypertriglyceridaemia and increased fat oxidation are the main features of altered fat metabolism encountered in this state. The endogenous catabolism of sepsis can be reduced by administering exogenous lipid emulsions as a source of metabolic fuel, although the changes in lipid metabolism associated with sepsis may affect the handling of these exogenous lipids. An exciting area for future research is an examination of the ability of lipid emulsions to reduce the morbidity and mortality associated with sepsis by altering immune responses, in addition to limiting catabolism.

Septicaemia is a major cause of morbidity and mortality among critically ill patients[1]. In the United States alone, the incidence of septic shock is 200 000 per annum[2] and in 40 per cent of these cases Gram-negative organisms are the cause[3]. Lipid metabolism is altered in septic shock; Gram-negative septicaemia can induce profound changes[4–6] (*Table 1*). Some abnormalities result from failure of specific organs, while others are part of a host response. Increasingly, artificial nutrition is used to meet the raised metabolic fuel demands in affected individuals, and lipids have become an important source of this fuel. The regulation of lipid metabolism in the patient with sepsis is complex and still unclear. In this review an attempt is made to elucidate the mechanisms influencing this regulation, the consequences for the host and the relevance in terms of nutritional support.

Sepsis and endotoxaemia

The human colon is a common source of Gram-negative septicaemia[3,9] because of its large bacterial content[10,11]. Normally bacteria are kept in the bowel lumen by a mucosal layer which acts as a defensive barrier. This barrier may be damaged as a result of inflammatory bowel disease[12–14], haemorrhagic shock[15–17], trauma[18] or reperfusion injury[19]. The damaged mucosa leads to increased permeability to bacteria and toxins[20]. Most of the bacteria entering the lymphatic system are phagocytosed locally by the reticuloendothelial system and those entering the portal circulation are dealt with by Kupffer cells. The urinary tract[21] and the upper gastrointestinal tract[22] are also significant sources of bacteraemia. When Gram-negative bacteria are phagocytosed their cell wall components may be released into the circulation, resulting in endotoxaemia. However, it is not uncommon to find endotoxaemia in the absence of Gram-negative bacteraemia[23–25]. In 30 per cent of cases the source of sepsis cannot be identified[26].

Endotoxaemia and cytokines

In experimental studies both humans and baboons produce a number of cytokines when challenged with endotoxin[27–29]. Important among these are tumour necrosis factor (TNF) α, interleukin (IL) 1 (α and β) and IL-6. Their appearance in the plasma has a well defined temporal relationship indicative of a ‘cytokine cascade’. TNF appears to be the first factor in this cascade (it is the first to appear), followed by IL-1 and IL-6[30]. Cytokines are important mediators of septic shock, having a pivotal role in regulating host response to sepsis[31–34]. Some cytokines can be detected only in septic shock, whereas others show a marked increase in plasma concentration during sepsis[25,35,36]. The correlation between mortality rate and cytokine levels in these patients is not always clear-cut[37]. Some cytokines (TNF-α, IL-1α and IL-1β) are thought to be produced in paracrine fashion[38], and so their plasma levels may not correlate with their action, while others (IL-6) have a more systemic function[39]. Most cytokines

---

Paper accepted 27 March 1996

Table 1 Effect of sepsis on lipid metabolism as shown by the concentrations of glycerol, non-esterified fatty acids and triacylglycerol, and the rate of appearance of glycerol and non-esterified fatty acids

	Plasma glycerol concentration (μmol l⁻¹)[7]	Rate of appearance of glycerol (μmol kg⁻¹ min⁻¹)[8]	Plasma NEFA concentration (μmol l⁻¹)[5]	Rate of appearance of NEFA (μmol kg⁻¹ min⁻¹)[8]	Plasma TAG concentration (μmol l⁻¹)[5]
Normal subjects	70(4) ($n = 16$)	2·4(0·2) ($n = 5$)	970(270) ($n = 5$)	6·5(0·8) ($n = 5$)	1250(100) ($n = 5$)
Patients with sepsis	130(22) ($n = 7$)	6·3(1·1) ($n = 12$)	6450(1600) ($n = 13$)	13·1(3·0) ($n = 12$)	5020(970) ($n = 13$)

Values are mean(s.e.m.). NEFA, non-esterified fatty acid; TAG, triacylglycerol have their own individual receptors, which are normally located on the cell membrane[40]. Cytokines bind to the extracellular domain of their receptor and activate intracellular tyrosine kinases. Once the signal is initiated, the cytokine with its extracellular component of receptor dissociates and forms a soluble complex, which can be detected in the plasma. Some cytokines can modulate their activity through their plasma antagonists[41–44]. The distal members of the cytokine pathway can downregulate the activity of the more proximal members[45], either directly[28,46] or indirectly via hormones[30,47–50].

Over the past few years there has been a rapid expansion in the field of cytokine analysis and currently well over 50 cytokines can be detected in plasma. However, the exact role of these newly discovered cytokines remains to be defined. It is likely that at least some of them will exert an effect on lipid metabolism, either through the hypothalamic–pituitary–adrenal hormone axis[47,51–53] or by altering the haemodynamics of various tissues that participate in lipid metabolism[54,55].

Tumour necrosis factor α

TNF-α is produced by a number of different cells including monocytes, macrophages and adipocytes[56]. It is a peptide (17 kDa) and in plasma exists as a trimer[57]. Lipopolysaccharide of Gram-negative bacteria is the most potent stimulator of its production but viral, fungal and parasitic infections can also act as stimulators[58]. It exerts its effect by binding to specific receptors[59] that activate tyrosine kinase[40]. It has profound metabolic effects, some mediated by hormones, others more directly[28,60,61]. In addition, it can stimulate the production of other cytokines (IL-1, IL-6 and IL-8).

Interleukin 1

There are three distinct species of IL-1 (IL-1α, IL-1β and IL-1 antagonist). They are produced by activated mononuclear phagocytes either under the influence of lipopolysaccharide or TNF. They can directly affect various tissues by binding to cell surface receptors[32]. They can influence the production of other cytokines and can also increase the plasma concentrations of adrenocorticotrophic hormone, cortisol, adrenaline, noradrenaline and glucagon[30,52,53,62].

Regulation of fat metabolism in healthy adults

Adipose tissue stores metabolic fuel in the form of triacylglycerol (TAG). This is by far the largest store of energy as up to a quarter of body-weight can be adipose tissue[63]. A TAG molecule is made up of three fatty acids attached to a glycerol backbone.

After a meal containing fat, TAG molecules are assembled in the enterocytes and extruded as part of a lipoprotein particle (chylomicron–TAG). When these particles pass through the adipose tissue capillaries their TAG content is hydrolysed by lipoprotein lipase (LPL), thereby releasing fatty acids which may be stored in the adipose tissue[64]. In the late postprandial period part of this stored fuel needs to be mobilized. To achieve this an intracellular lipase, hormone-sensitive lipase (HSL), becomes increasingly active. In the adipose tissue the stored TAG is hydrolysed by HSL to produce non-esterified fatty acids (NEFAs) and glycerol[65]. These NEFAs are released into the general circulation from where they are extracted by either the liver or the muscle. In liver, NEFAs are either oxidized or re-esterified to produce TAG. TAG is repackaged with very low density lipoprotein (VLDL) into VLDL–TAG particles, before being released into the general circulation. This VLDL–TAG is hydrolysed in the muscle capillaries by LPL to yield more fatty acids. All these fatty acids are either oxidized directly[66] or stored in the muscle TAG pool[67]. Adipose tissue LPL activity is regulated by plasma insulin levels[68] and is reciprocally linked to muscle LPL activity[69,70]. Adipose tissue HSL activity is inhibited by insulin and stimulated by catecholamines, cortisol and growth hormone[71]. The pathways for mobilization and deposition of fat are summarized in *Fig. 1*.

Fat metabolism in sepsis

The pattern of responses to noxious stimuli has been well defined in terms of ebb and flow phases[72], but in sepsis these phases are less clearly defined[73,74] and so their impact on metabolism is more complex. Fat is the preferred fuel for oxidation in patients with sepsis[8,75,76] and this oxidation cannot be suppressed to the same level with glucose infusion as it can in healthy subjects[77–79]. The high resting energy expenditure in sepsis is accompanied by increased NEFA and glycerol turnover[79,80]. One determinant of the rate of fat oxidation is the plasma NEFA concentration which, in turn, is regulated by fat mobilization[81–83]. In patients with sepsis fat mobilization is far greater than fat oxidation[84], implying considerable cycling[85]. Hormonal perturbations alone have not been

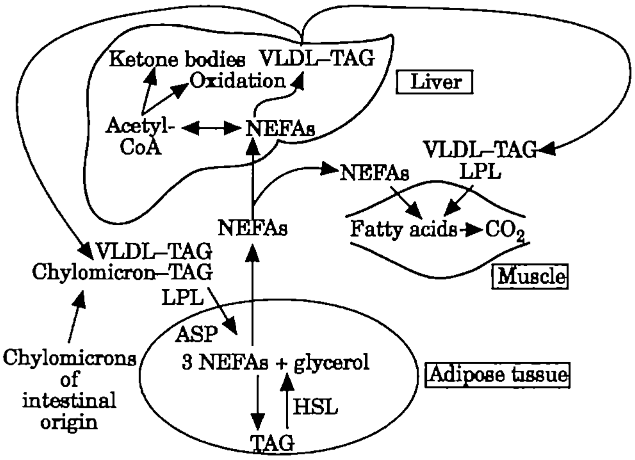

Fig. 1 Normal pathways of lipid metabolism. In the postabsorptive state, lipolysis of triacylglycerol (TAG) stored in the adipose tissue by hormone-sensitive lipase (HSL) yields non-esterified fatty acids (NEFAs). These are removed from plasma by either the muscle or the liver. In the liver, fatty acids can be either oxidized or re-esterified to produce very low density lipoprotein–TAG (VLDL–TAG), which is secreted. VLDL–TAG is hydrolysed by muscle or adipose tissue lipoprotein lipase (LPL) to yield fatty acids, which can be either oxidized in the muscle or stored in the adipose tissue. In the postprandial state dietary TAG in the form of chylomicron–TAG is hydrolysed by the adipose tissue LPL and the fatty acids are directed into the adipose tissue for storage as TAG. This may be reinforced by locally produced acylation-stimulating protein (ASP). CoA, coenzyme A; CO_2, carbon dioxide

able to account for all the metabolic effects seen in sepsis[86,87]; thus the possible role of other mediators was proposed long before the identification and isolation of cytokines[88].

Metabolism of non-esterified fatty acids

NEFAs are released by peripheral adipose tissue to provide metabolic fuel. In patients with sepsis plasma NEFA concentrations are usually raised[5,89], although normal or depressed[90] concentrations have occasionally been observed. Endotoxin challenge to animals results in raised plasma NEFA levels[91,92].

Plasma levels of NEFAs are regulated by lipolysis and adipose tissue blood flow[93]. Endotoxin increases plasma NEFA concentration via its effects on cytokines and hormones. TNF-α is the first cytokine to be released in response to endotoxin; it can increase lipolysis directly[61] as well as indirectly through other hormones[60]. Other cytokines lower down the cascade have been shown to have similar indirect effects, both in animals[94] and humans[62]. Adrenaline[95,96], noradrenaline[97] and cortisol[98] can stimulate lipolysis, thereby increasing plasma NEFA concentrations. Catecholamines can increase adipose tissue blood flow[99 100] and their concentrations in patients with sepsis are raised grossly[101]. Increased plasma ketone body concentrations suppress lipolysis[102] and in sepsis the low levels of ketones may also contribute to increased lipolysis[103]. In patients with sepsis, increased lipolysis and adipose tissue blood flow result in increased plasma NEFA concentration. The increased lipolysis in sepsis depletes the intracellular TAG stores and may contribute to cachexia.

The rate of fat oxidation is determined by the plasma concentration of NEFA[83,92,104]. In sepsis the raised NEFA concentration leads to greater fatty acid oxidation. The low value of respiratory quotient so often seen in patients with sepsis reflects their increased rate of fat oxidation[75].

In some animal models where the insult is particularly severe, low levels of plasma NEFAs have been observed in association with reduced fat oxidation[105]. In these cases adipose tissue perfusion is reduced[106] and less albumin is presented to the adipose tissue, thereby reducing the facility for NEFAs to be transported into the general circulation[107]. A severe reduction in tissue perfusion also leads to anaerobic metabolism and raised lactate levels, which can further suppress lipolysis[108,109].

Metabolism of triacylglycerol

It has long been known that animals injected with bacteria show gross hyperlipidaemia[110,111]. Analysis of lipid fractions has revealed that sepsis can induce hypertriglyceridaemia, mainly through raised VLDL concentrations[91,112,113]. The increase in plasma VLDL–TAG concentration could be due to either increased production by the liver or decreased clearance by peripheral tissue.

Animal studies have shown that the hepatic TAG output can increase by 50 per cent within 2 h of endotoxin challenge[114], and both TNF-α and IL-6 can increase hepatic lipogenesis[98,115]. In humans, hypertriglyceridaemia can be induced in a similar manner by administration of TNF-α or interferon γ[116,117]. This rise in hepatic TAG production is probably mediated by a number of cytokines and hormones, as both anti-TNF and anti-interleukin antibodies fail to suppress endotoxin-induced hypertriglyceridaemia[118,119]. The increased adipose tissue lipolysis in response to endotoxin and cytokines provides increased quantities of fatty acid for TAG synthesis. This rise in plasma NEFA levels alone cannot account for increased hepatic TAG production, as catecholamine-induced lipolysis fails to raise plasma TAG levels. Some animal studies have shown that *de novo* synthesis of fatty acids in the liver is increased after endotoxin administration, but it can still account for only 10 per cent of the TAG of hypertriglyceridaemia[120]. In humans *de novo* synthesis of fatty acids in liver can account for only 1–2 per cent of VLDL–TAG production[121] and its role in sepsis is probably insignificant. It is more likely that during sepsis most of the fatty acids in liver are re-esterified, rather than oxidized, resulting in increased VLDL–TAG synthesis[122].

Plasma VLDL levels can also be increased because of impaired clearance due to reduction in LPL activity. Both muscle and adipose tissue biopsies taken from patients with sepsis have shown reduced LPL activity[68], and animals with sepsis show decreased TAG clearance when exogenous lipid is infused[91,123]. *In vitro* studies have shown that TNF-α, also known as cachectin, is able to suppress LPL activity in adipocyte (3T3-L1) cell lines[124] and subsequently it has become clear that endotoxin can suppress LPL activity through TNF-α production[125,126]. Further studies showed that vascular endothelium was essential for LPL suppression by TNF-α[127], as TNF-α failed to alter LPL activity in isolated adipocytes despite the fact that TNF-α was bound to cell surface receptors[128]. The reduction in the LPL activity in patients with sepsis might imply reduced lipid clearance, but exogenous lipid infusion studies have indicated increased lipid clearance[129]. One possible explanation is that in patients with sepsis tissue blood flow is increased; thus, despite low LPL activity, lipid clearance by adipose and muscle tissue is increased. LPL action is dependent on the type of tissue as well as the nutritional state of the individual[130–132]. The most likely explanation is that the hypertriglyceridaemia of sepsis is caused by a combination of increased TAG production by the liver and decreased VLDL clearance by the peripheral tissue, as summarized in *Fig. 2*.

Adipocytes are capable of producing TNF-α and it has been proposed that they regulate their own mass through TNF-α-induced changes in LPL activity[56,133,134]. This hypothesis of autoregulation has been strengthened by the fact that obese subjects exhibit higher levels of TNF-α messenger RNA in adipose tissue[135]. It is likely that during endotoxaemia this autoregulation breaks down, resulting in loss of fat mass. In patients with sepsis the action of cytokines and hormones on adipose tissue can deplete intracellular TAG stores. In addition, there is a further failure to replenish these stores. The levels of C3a-des-arg, also known as acylation-stimulating protein (ASP), are reduced in sepsis as a result of activation of coagulation and complement pathways[136,137]. ASP acts in concert with adipose tissue LPL to direct fatty acids to esterification and storage[138,139]. Hence, in sepsis the mechanism of fatty acid uptake is impaired and, in addition, the amount of fatty acid available for uptake by the adipose tissue is reduced because of low LPL activity[68,125].

Ketone bodies

Ketone bodies are produced from the oxidation of NEFAs in the liver as an alternative form of metabolic

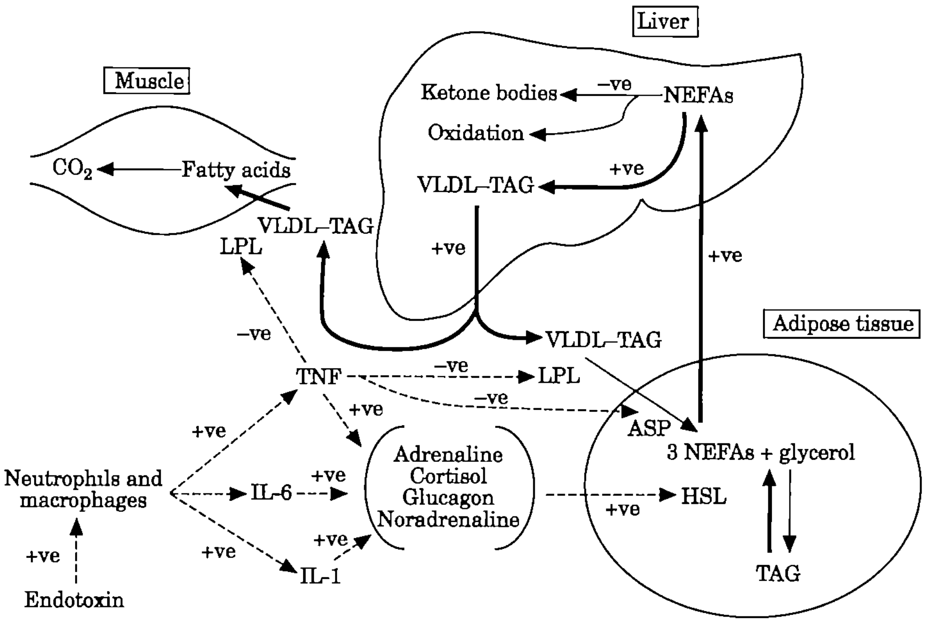

Fig. 2 Effect of sepsis on lipid metabolism. In the liver most fatty acids are re-esterified rather than oxidized. The increased amounts of very low density lipoprotein (VLDL) generated by the liver are poorly cleared by the peripheral tissues because lipoprotein lipase (LPL) activity is reduced by tumour necrosis factor (TNF). In addition VLDL–triacylglycerol(TAG) production may be raised because of increased lipolysis in adipose tissue. Dashed arrows show regulatory pathways. CO_2, carbon dioxide; NEFAs, non-esterified fatty acids; HSL, hormone-sensitive lipase; ASP, acylation-stimulating protein

fuel. In liver, fatty acids are either esterified into TAG or they undergo β-oxidation to yield acetyl coenzyme A (CoA), which can be either completely oxidized or converted into ketone bodies by the hydroxymethylglutaryl–CoA pathway. In starvation, as the plasma NEFA concentration rises, there is increased conversion of NEFAs into ketone bodies[140]. Hormones that stimulate lipolysis also increase plasma ketone body concentrations. However, in sepsis ketone body production is suppressed, despite raised glucagon, cortisol and catecholamine concentrations[141,142], and its suppression cannot be explained by the increased plasma insulin levels alone[143]. Animal studies have shown that both TNF-α and IL-1 can suppress plasma ketone body concentrations in a similar manner to endotoxin[144]. This antiketotic effect of cytokines is likely to be direct, as they increase plasma levels of lipolytic hormones, which would increase plasma NEFA concentrations. The most likely explanation for the suppression of ketone body concentration in sepsis is that fatty acids undergo esterification in the liver (to produce TAG), rather than β-oxidation. An important difference between sepsis and starvation is that in the former plasma TAG levels are raised and in the latter ketone body levels are increased.

Role of hypertriglyceridaemia in sepsis

It is thought that hypertriglyceridaemia is a protective response initiated by the host to counter various biological assaults, in addition to providing a readily available source of energy[145]. It is well known that lipids can bind endotoxin and thereby render it ineffective[146–148]. Most lipoproteins can bind to endotoxin in proportion to their concentration in plasma, and such complexes appear to be stable[149]. More detailed animal studies have revealed that endotoxin becomes an integral part of VLDL *in vivo*, whereas the other lipoproteins are simply bound to it[150]. Although lipoproteins have been shown to have a protective effect against endotoxins in *in vitro* studies, the only study in which hyperlipidaemia was induced with simultaneous endotoxin administration in humans showed that the systemic inflammatory response was potentiated[151].

Exogenous lipids in the nutritional management of patients with sepsis

The increased metabolic fuel demand of patients with sepsis can be met by fatty acids derived from exogenous lipid emulsions[129,152,153]. The major advantage of lipid emulsions over alternative sources of metabolic fuel is their high energy content and low osmolarity. They have a similar effect to glucose in reducing nitrogen loss[84,154–156], but without the added effect of carbon dioxide overload[157]. Lipid emulsions can also alter the phospholipid composition of the cell membranes[158,159], thereby modifying their behaviour.

However, lipid emulsion can exacerbate the hypertriglyceridaemia of sepsis and can lead to even higher concentrations of plasma NEFAs. The hypertriglyceridaemia can interfere with reticuloendothelial[160–162] and pulmonary[163–165] function. Myocardial function can be depressed by hypertriglyceridaemia[166] and the high concentrations of plasma NEFAs can potentially lead to cardiac arrhythmias[167]. The factors that lead to hepatic dysfunction in sepsis are poorly understood[168,169] but balanced nutrition, which includes lipid, can be safely given to patients with hepatocellular damage[170,171].

Lipids can be administered on their own or in combination with glucose and amino acids. If the intake of a substrate exceeds its oxidation capacity, the substrate will accumulate and may cause adverse effects. In practice, the contribution of lipids to the non-protein energy intake should be 30–60 per cent, as excessive lipid administration (i.e. greater than 70 per cent of total energy expenditure) results in increased fat storage[172]. Excessive energy input should be avoided as it has little added effect on nitrogen balance[80,173] and can lead to increased mortality in sepsis[174–177]. Mortality and morbidity rates can potentially be improved in patients with sepsis by providing them with the optimum amount of energy, and maximum benefit can be achieved by combination of different nutrients.

Enteral versus *parenteral*

Lipids can be administered parenterally or enterally; in general the enteral route is associated with fewer complications[178–182]. The main advantage of enteral nutrition is the presence of nutrients within the gut lumen, which is essential for maintaining the gut barrier and immune competence[183,184]. It can also reduce the risk of secondary sepsis in injured patients[180,185] by preventing the overgrowth of gut bacteria[186]. In sepsis, impaired gut mucosal blood flow leads to a reduction in nutrient absorption capacity[187–189]. This can potentially be restored by early enteral nutrition[190]. However, in patients with sepsis the route of nutrient administration may not prevent multiorgan failure[191]. In some patients enteral nutrition may be of only limited use because of primary gut dysfunction.

The main advantage of parenteral nutrition is that it can be given in the presence of gut dysfunction. In addition, the nutrient and energy input can be varied and tightly regulated. However, parenteral nutrition can lead to a severe form of cholestatic jaundice[192,193] and mucosal atrophy[194]. Mucosal atrophy can lead to amplified cytokine and hormonal response during secondary sepsis[195].

The major advantage of lipid solutions is their low osmolarity, allowing them to be administered by a peripheral rather than a central route[196]; this reduces complications associated with central venous nutrition[197,198]. Parenterally administered lipids behave in a similar manner to endogenous lipid because of their ability to acquire apolipoproteins rapidly[199,200]. Finally, the route of nutrition administration in a particular patient with sepsis should depend not only on clinical features but also on available resources.

Long versus *medium-chain triglycerides and selective fatty acids*

TAG is the main lipid constituent of exogenously administered lipid emulsions. Traditionally, the TAG of most lipid solutions contained long-chain (C_{16}–C_{18}) triglycerides (LCTs), but in recent years a number of preparations have become available with medium-chain (C_8–C_{10}) triglycerides (MCTs). Medium-chain fatty acids are more rapidly oxidized than long-chain fatty acids[201,202] because they do not require specific transport mechanisms to enter mitochondria for oxidation.

The metabolic response appears to be different when a combination of MCTs and LCTs is administered rather than LCTs alone. The MCT–LCT combination leads to greater plasma levels of NEFAs and glycerol, as well as an increased plasma insulin concentration[203,204]. Medium-chain fatty acids cannot be re-esterified in the liver; therefore MCT solutions produce a greater ketone body response[205,207] and this can have an additional nitrogen-sparing effect[208,209]. The greater protein-sparing role of MCT has been demonstrated in surgical patients[210], but other studies have shown no clear advantage[155,211].

The intermittent administration of LCTs can lead to impaired reticuloendothelial function and this can be prevented with the use of MCTs[162]. Therefore, the reduction seen in immunological function is smaller with MCT use than with LCT[212,213]. The combination of MCTs and LCTs can reduce the incidence of cholestatic jaundice associated with parenteral nutrition[214]. The medium-chain fatty acids have a trophic effect on the proximal jejunal mucosa, whereas long-chain fatty acids have their effect on the middle part of the jejunal mucosa[215]. Thus a combination of MCTs and LCTs can be used to maximize the trophic effect. In addition, medium-chain fatty acids can reduce bile output, and so can reduce the cathartic effect of bile acids on the colon, preventing diarrhoea[216]. Recently, structured TAGs have become available for clinical use[217]. In these, TAGs are composed of a mixture of medium- and long-chain fatty acids. The theoretical advantage of these structured TAGs over the MCT–LCT combination emulsions is slow and sustained release of medium-chain fatty acids.

Fatty acids play an important role in regulation of the immune response. The plasma profile of fatty acids reflects the composition of exogenously administered lipids[218]. As a result, the immune response can be manipulated by varying the composition of different fatty acids in the lipid solution. A number of *in vivo* studies have shown that *n*-3 polyunsaturated fatty acids are potent inhibitors of lymphocyte proliferation[219,220]. *In vitro* studies have confirmed, in healthy volunteers, that the cytokine response to endotoxin can be modified by *n*-3 fatty acids[221–224]. Dietary manipulation of fatty acids has led to changes in the survival of septic animals[224] and clinical studies have shown that *n*-3 fatty acid administration can lead to a reduced hospital stay[225]. Manipulation of the *n*-3 : *n*-6 fatty acid ratio can lead to amplification or suppression of the immune response[226]. It seems possible that morbidity and mortality rates in patients with sepsis will, in the future, be reduced by optimizing nutritional

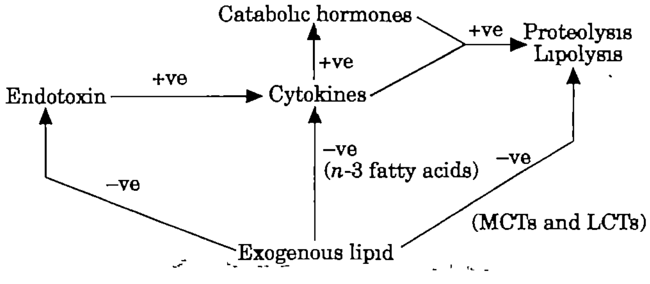

Fig. 3 Interactions of exogenous lipid emulsion and endogenous metabolic alterations in patients with sepsis. Exogenous lipid emulsion particles are similar to very low density lipoprotein particles and can potentially bind endotoxin, thus reducing its effect. The medium-chain triglycerides (MCTs) and long-chain triglycerides (LCTs) liberate fatty acids, which can be used to provide metabolic fuel. The increased plasma levels of non-esterified fatty acids can inhibit endogenous triacylglycerol lipolysis, thereby preserving not only fat fuel but also lean body mass. The *n*-3 fatty acids in the lipid emulsion may reduce the excessive cytokine response seen in some patients with sepsis

input and manipulation of the immune response, as summarized in *Fig. 3*.

Management of nutrition-induced lipaemia in patients with sepsis

Gross lipaemia occurs in some patients with sepsis receiving parenteral nutrition, although it is rare in those receiving enteral nutrition. It may reflect the supraphysiological rate of entry of lipoprotein particles from the exogenous lipid infusion, in combination with compromised clearance of lipoprotein–TAG from the plasma[68]. The management of such patients has been discussed by Nordenström[227]. Their lipid tolerance should be assessed regularly by inspection of plasma for turbidity and measurement of plasma TAG concentration[228,229]. The lipid infusion rate must be decreased during episodes of hypertriglyceridaemia, although lipid tolerance is likely to change rapidly and should be assessed from time to time as above. More common than hypertriglyceridaemia is the occurrence of hypercholesterolaemia during lipid infusion. This represents the formation of an abnormal lipoprotein particle, lipoprotein X, during intralipid infusion[230,231]. Lipoprotein X is similar to low density lipoprotein but is cleared slowly by the liver[232]. Its formation is favoured by infusion of a 10 per cent lipid emulsion because of the high phospholipid : TAG ratio. Thus, its formation can be reduced by substituting 10 per cent with 20 per cent lipid emulsion[233]. It should also be borne in mind that turbidity in plasma can interfere with some common laboratory tests[234], so close liaison with the clinical biochemistry laboratory is essential.

Summary

Septic shock produced by Gram-negative organisms is a common surgical phenomenon. It can produce profound changes in lipid metabolism, but the mechanisms that induce these changes are poorly understood. Some are brought about by hormones, whereas others are induced by cytokines released in response to endotoxaemia. Optimal nutritional support is essential to meet the metabolic demands of patients with sepsis and lipid emulsions are being used increasingly as a source of this support. Such emulsions not only provide nutrition but are also a powerful means of altering the immunological response of the host.

However, there is still a dearth of knowledge about the mechanisms that lead to lipid abnormalities in patients with sepsis, and about the role of exogenous lipid emulsions as a source of metabolic fuel and regulator of the immunological response. Further research in this area holds the promise of reducing morbidity and mortality rates in such patients.

Review

Laparoscopic inguinal hernia repair

M. S. L. LIEM and TH. J. M. V. VAN VROONHOVEN

Laparoscopic inguinal hernia repair may cause a revolution in general surgery if it proves to be the best treatment for inguinal hernia. Today there are several laparoscopic techniques that have been shown to be feasible. However, no information concerning long-term recurrence rates and cost-effectiveness is available. This review summarizes current knowledge, including all randomized studies that have appeared hitherto, and concludes that it is still premature to advocate a transition from the preferred individualized conventional technique to a laparoscopic technique on a large scale. However, a definite statement on the place of laparoscopic repair may be given in the near future in the light of larger randomized studies.

Considering the growing literature on laparoscopic hernia repair, one might easily be tempted to conclude that it is already an accepted procedure; at this time such a conclusion is premature and based on insufficient research. The quest for the optimal treatment of inguinal hernia was given new vigour after the introduction of minimally invasive surgery. This was enhanced by the media, which stimulated a patient preference for the new minimally invasive technique, and by surgeons' fear of being left behind. Different laparoscopic techniques have emerged, some successful, others not[1,2]. Not all surgeons have supported this new development[3,4] and, more importantly, it has generally been recognized that adequate research should be performed before the world-wide acceptance of this 'controversial' technique[5–8]. Randomized trials were initiated, but so far all reported studies are preliminary, lacking sufficient power; in only one has the newest and conceptually promising totally extraperitoneal technique been used[9–15].

Now, more than 5 years after the introduction of laparoscopic inguinal hernia repair, where do we stand? Are there really significant advantages compared with conventional techniques? If so, which laparoscopic technique should be applied and for what type of hernia? Are we yet confident enough to accept the new technique, or should we wait for the long-term results of the well designed, large, prospective randomized trials that are now in progress?

Methods

This review has employed a database in which all articles included in Medline (Bethesda, Maryland, USA) (on silver platter) concerning inguinal hernia from 1966 to 1994 were stored (search with 'hernia-inguinal/all subheadings'). An update was made in early 1996 with the 1995 edition for 1993–1995. In addition, articles from 14 leading surgical journals published in 1994, 1995 and early 1996 were screened for 'laparoscopic herniorrhaphy'.

Conventional hernia repair

There are numerous conventional techniques used to repair an inguinal hernia[16]. Excellent results (i.e. recurrence rates of less than 2 per cent with follow-up of over 5 years) from specialized hernia centres using their own techniques have been reported[17–20] but, unfortunately, in most of these studies details and appropriate methods concerning follow-up are lacking. Others have recognized these deficits and emphasize the importance of complete and reliable follow-up[20–22]. Moreover, for general surgeons the excellent results reported by specialized centres do not appear to be reproducible in well controlled studies[22–25]. This is confirmed by annual statistics from various countries which always show that 10–15 per cent of inguinal hernia operations are for recurrent hernias[20,26–28]. Another interesting problem is the socioeconomic burden for society of conventional inguinal hernia repair. In the Netherlands, patients with paid employment return to work after an average of 4–6 weeks[29]. Most other countries are no different[30,31]. It would appear that there is room world-wide for improvements in the treatment of inguinal hernia.

Current laparoscopic techniques (*Fig. 1*)

Others have described the history and (early) laparoscopic techniques at length[32–35]. Currently, four techniques, a transabdominal preperitoneal (TAPP) approach, a totally extraperitoneal (TEP) approach, an intraperitoneal onlay mesh (IPOM) technique and simple closure of the internal ring, are still being performed and are discussed here briefly. The first three of these methods are based on the principle of using a mesh prosthesis to cover the defect of the abdominal wall from the inside (*Fig. 1*). The last technique, in which a staple or stitch is used to narrow the internal ring[36], can be used only in small to moderate indirect hernias. It is performed by a few surgeons in a minority of cases (2 per cent) and so any further discussion of this method has been omitted.

A study[37] in the early phase of the development of laparoscopic techniques reported a TAPP technique in 65 per cent of cases and an IPOM repair in 25 per cent. A more recent compilation of over 2500 patients reported a shift in the distribution of these techniques: the TAPP

Paper accepted 3 May 1996

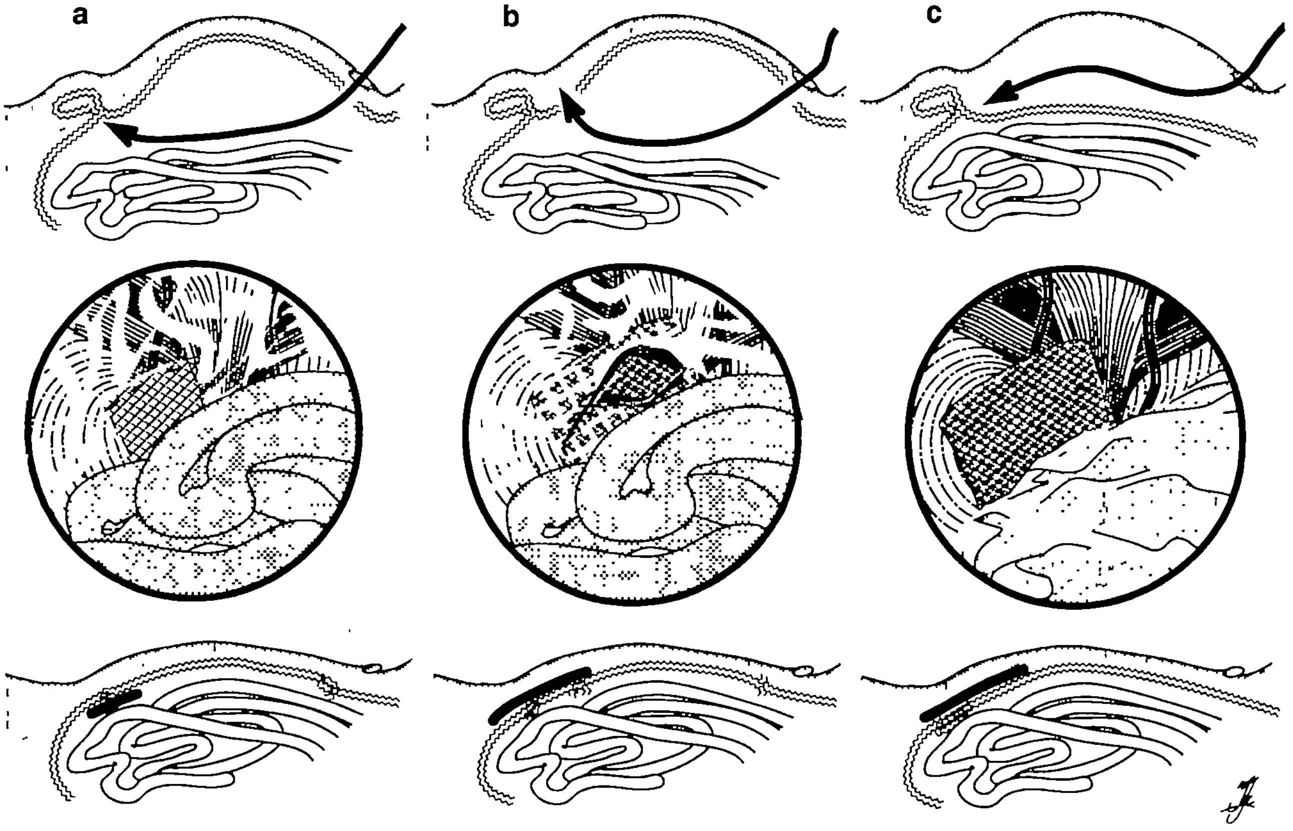

Fig. 1 Current laparoscopic techniques. a Intraperitoneal onlay mesh technique: placement of mesh inside the peritoneum. b Transabdominal preperitoneal technique: preperitoneal placement of mesh through a peritoneal incision. c Totally extraperitoneal technique: preperitoneal placement of mesh without entering the abdomen. Upper panel – approach by pneumoperitoneum (a and b), and by pneumopreperitoneum (c); middle panel – laparoscopic view after mesh placement; lower panel – situation after mesh placement

technique is performed most frequently (60 per cent), followed by the TEP approach (18 per cent) and the IPOM repair (11 per cent)[38]. Thus, there appears to be a preference for mesh placement in the preperitoneal space, in accordance with the ideas of Stoppa[39].

Placement of mesh inside the peritoneum

The IPOM repair can be performed with a low-pressure pneumoperitoneum and so, potentially, under local anaesthesia. The hernia defect is easily recognized and cleared of intestines and adhesions with minimal dissection, making it a relatively easy procedure. The hernia orifice is then covered with intraperitoneally placed polypropylene or expanded polytetrafluoroethylene mesh (size between 7·5 × 7·5 cm and 10 × 15 cm)[13,33,40,41] which is secured with staples, mainly to the peritoneum and to the pubic tubercle and Cooper's ligament. Some of the objections against this method are[32,34]: (1) it cannot be used for medial defects, as the mesh is stapled only medially on to the peritoneum and peritoneum with mesh can still migrate through the hernia orifice into the defect; (2) the structures under the peritoneum cannot be seen accurately, thus when stapling there may be a risk of damage to these structures; and (3) although a laparoscopically placed mesh seems to induce fewer adhesions than mesh placed at laparotomy[42], severe complications (bowel obstruction and fistula formation) have been reported. The conversion rate to a conventional repair varies between 0 and 7 per cent. Mean operating time ranges from less than 20 min to 49 min for unilateral inguinal hernias.

Preperitoneal placement of mesh through a peritoneal incision

After the creation of a pneumoperitoneum, a peritoneal incision is made above the hernia defect to enter the preperitoneal space. Sufficient preperitoneal dissection is necessary to cover the musculopectineal orifice of Fruchaud (the area where all potential hernial defects occur) with a mesh prosthesis. The size of the mesh varies between 7 × 12 cm and 10 × 15 cm. In most cases the mesh is fixed with staples. Afterwards, the peritoneum is closed with either staples or stitches. In a minority of cases it is necessary to convert to an open conventional technique (less than 4 per cent). The TAPP technique is the most reported method, but the majority of authors have not compared it with a standard conventional operation. Additionally, the studies have a short-term follow-up, sometimes only by telephone interview (*Table 1*)[43–49]. Some authors have made a non-randomized comparison with conventional techniques (Bassini and Shouldice) and so-called tension-free techniques[50–53]. Mean operating time varies between 35 and 90 min for unilateral hernias and between 70 and 110 min for bilateral inguinal hernias.

Preperitoneal placement of mesh without entering the abdomen

In the newest technique, the TEP approach, the peritoneal cavity is not entered but the preperitoneal space is selectively developed through a subumbilical incision[54–56]. In some studies a dissection balloon is used to facilitate preperitoneal dissection[57], but this can also be done with a Foley catheter[58]. The preperitoneal space is usually maintained with a carbon dioxide pneumopreperitoneum. With the use of an abdominal wall lift this method can be performed without the need for such a pneumopreperitoneum[59]. An endoscopically guided surface repair, which may be less demanding, has also been proposed[60]. After sufficient preperitoneal dissection a mesh prosthesis (size between 8 × 10 cm and 10 × 15 cm) is positioned and, in most cases, fixed with staples; the preperitoneal space is desufflated. The TEP approach is technically more difficult than the others, but it avoids the potential risk of damaging intra-abdominal organs, and it may save time and cost as it is not necessary to incise and close the peritoneum from the inside[2,61]. The conversion rate to another technique, either TAPP or conventional, varies between 4·4 and 8 per cent during the learning curve. Mean operating time is between 42 and 90 min for patients with either unilateral or bilateral inguinal hernias.

Postoperative pain and disability

Hospital stay has been found to be similar for all laparoscopic techniques, most patients being discharged within 24 h. The median hospital stay was between 1 and 3 days. One exception is a German study by Sandbichler *et al.*[46], but their 4 days compare favourably with their 7 days after a conventional repair in the same timeframe. Most of these preliminary studies have focused on technique and complications, but many have also reported minimal use of analgesics, with some patients not requiring postoperative analgesia at all and achieving a successful resumption of daily activities within about 1 week. Unfortunately, both hospital stay and return to normal activity may be associated with surgeon and patient preference; common practice with respect to these issues varies from country to country, which makes comparisons difficult[7]. Some studies have measured postoperative pain. Patients were generally pain-free by 1 week after operation[44,57] and, defining resumption of daily activity by the number of days needed after operation before regaining the ability to drive a car, they returned to normal twice as fast as after a Lichtenstein repair[52]. It is important to note that in none of these studies was a questionnaire to measure activities of daily life or quality of life used.

Complications

Complications may be related to laparoscopy itself, such as lesions caused by needle or trocar insertion (which are quite rare) and events related to pneumoperitoneum (hypercarbia and cardiopulmonary effects)[62–65]. The first does not really apply to the TEP technique, as in this method only the preperitoneal space is opened and developed under vision. However, a pneumopreperitoneum is necessary to maintain the preperitoneal working space and this may result in the development of a rapid and more severe hypercarbia[66,67], although this is not universally acknowledged[68].

Complications related to hernia repair itself include subcutaneous emphysema in the scrotum or lower abdominal wall, scrotal or trocar-site haematoma, seroma, wound infection and neuralgia[38,69]. In most cases neuralgia is a transient complication. Complication rates vary between 8 and 12·4 per cent. Conversion to another technique – in most cases to a conventional approach, but for the TEP procedure it is also possible to convert to a TAPP approach – have been reported for all three laparoscopic operations; conversion is most frequent for the TEP technique[10,13,55].

More severe complications have also been described: meralgia paraesthetica by entrapment, either by fibrous tissue or (in most cases) by a staple placed into the nerve[70–73], and intestinal obstruction due to adherence of small bowel to mesh[74–77]. Naturally, nerve entrapment by staples cannot occur if the mesh is kept in place solely by intra-abdominal pressure, as has been advocated by some authors[29,39,61]. Intestinal obstruction caused by adhesions from bowel to mesh can theoretically not occur if a TEP approach is used, but can be encountered after a transabdominal approach as there is a possibility of mesh contact with bowel if the peritoneum is insufficiently closed. This seems to be confirmed by Phillips *et al.*[38], who collected data on serious complications from 23 surgeons. They reported on 1533 patients who underwent TAPP procedures, complicated in 2 per cent of cases by neuralgia, in 0·3 per cent by bowel obstruction and in two by death (one myocardial infarction and one hepatic failure); 367 patients who underwent TEP procedures had no serious complication.

Recurrences have been reported after all laparoscopic techniques, but are lowest after TEP repair[37,78,79]. Moreover, in a multi-institutional study no recurrences were noted after 578 TEP repairs, but no details about length of follow-up were given[80]. However, during the learning curve there may be a large difference between individuals in terms of recurrence rate, ranging from 0 to 20 per cent during the first 30 cases[61]. Reasons for early recurrences were, in fact, mostly surgical or technical errors. The most common reason was the size of the mesh being too small. It has been suggested that fixation is not necessary if the mesh size is large enough[81,82]. Indeed, not having to provide fixation not only saves time and money, but also obviates another serious complication, namely nerve entrapment by staples. Another frequent reason for a 'recurrence' is not recognizing or insufficiently isolating an indirect hernia because of insufficient anatomical knowledge, too limited dissection or reluctance to convert to another more appropriate technique. This may be encountered especially during the learning curve[80]. Better knowledge regarding the aetiology of early recurrence might lower the incidence of the causative errors.

Comparisons between laparoscopic techniques

Fitzgibbons *et al.*[37] reported on an international non-randomized multi-institutional trial in which the participating surgeons used their preferred technique. There was a 4·5 per cent recurrence rate after a mean follow-up of 23 months. Recurrences were recorded only after TAPP and IPOM repairs; none was noted after TEP repair. However, most TEP procedures were performed by a single surgeon. Recurrence rates for individual surgeons varied from 0 to 14·5 per cent. Although several previous studies had already produced similar results with laparoscopic techniques, the Fitzgibbons study has been suggested as more closely reflecting the value of laparoscopic repair in the population at large, as 21 investigators from both university and private practice settings participated[23].

Felix *et al.*[83] reported a large experience with both the TAPP and TEP techniques, and concluded that the TEP method may be the procedure of choice in most situations. Ramshaw *et al.*[84] concluded from a similar retrospective study that the TEP approach has significant advantages, but a relative contraindication for this technique may be previous lower abdominal surgery.

To enhance comparability there is agreement that hernia defects should be classified accurately in future studies; the Nyhus classification seems to be the most appropriate[85].

Which technique is best suited for which hernia?

Most authors agree on the suitability of laparoscopic repair for bilateral and (multiple) recurrent hernias[1,20,37,85]. No or only one additional port (for the TEP approach) is needed for a bilateral repair and so tissue trauma is less than that during conventional bilateral repair. A recent study of 150 patients having bilateral hernia repair using a TAPP approach reported good results with no recurrence after a median follow-up of 18 months[86]. In (multiple) recurrent hernias after previous conventional repairs the preperitoneal space is usually free from fibrous tissue and adhesions, allowing for an easy and safe dissection with a clear view of all the important structures. It has been suggested that a small indirect hernia can be treated well using an IPOM or TEP procedure, while a complicated recurrent one can be treated better with a TAPP technique. Incarcerated and large scrotal hernias, if they are to be handled laparoscopically at all, may best be dealt with by a TAPP approach[83]. There is so far no agreement about whether laparoscopic repair should be applied to the most common situation: the uncomplicated unilateral inguinal hernia. Nor is there agreement about which technique might best be used. Perhaps a strong patient preference to return to work as quickly as possible may be an exception[14]. All three techniques, but especially the preperitoneal (either TAPP or TEP), may prove useful for different types of hernia.

Evidence from randomized trials

Seven randomized trials have been published in the literature comparing open with laparoscopic hernia repair[9–15]. As all were initiated in 1992 or early 1993, only one has used the TEP technique, which at that time was performed by very few surgeons. All trials focused on short-term outcome measures with a short follow-up, so meaningful statements concerning recurrence rates are not available. All seven reports confirmed the observation of previous non-randomized studies to a greater or lesser extent: less postoperative pain, less use of analgesics and (in four trials) faster recovery after a laparoscopic repair than after an open operation. In the remaining three studies recovery was slightly better for patients in the laparoscopic group than for those having open repair, but this was not statistically significant (*Table 2*)[87].

Lawrence *et al.*[15] state that thousands rather than hundreds of patients should be included in randomized trials to detect differences in recurrence rates between laparoscopic and open repair. It is this outcome that has generally been considered the most important measure in the evaluation of hernia surgery[88]. For patients themselves it also seems to be the most relevant issue: 74 per cent of those in one study considered long-term recurrence the most important outcome measure, not the speed of recovery[15].

In two randomized studies quality of life was measured[14,15]. There is increasing interest in this outcome measure and it is now incorporated more frequently in surgical randomized trials[89]. Quality of life was measured with the Short-Form 36 questionnaire in one study and did not show differences for most dimensions, except pain, energy and social function. Interestingly, no difference for the dimension 'physical mobility at 10 days' was noted[15]. Another questionnaire, the Nottingham Health Profile, was applied by Barkun *et al.*[14], but the results of this were compared only with baseline and not with the conventional repair technique. Nevertheless, a greater improvement in quality of life has been noted by them after laparoscopic than after open repair. Several authors[7,10] have advocated the use of a more objective outcome measure, such as a physical performance test, to measure postoperative recovery, as return to work may vary with a patient's motivation, disability cover and external uncontrolled advice. Even in randomized trials there may be a bias if surgeons, family physicians and nurses tend to give different advice to patients after conventional repair than after laparoscopic repair[14].

Studies of cost are becoming increasingly important but, regrettably, in the field of minimally invasive surgery they have lacked scientific objectivity and are often based on data that are suspect[90]. In a true cost–effectiveness analysis within randomized trials, all relevant costs from a societal point of view and not just hospital charges[91,92] should be calculated and compared[93]. In two randomized trials, as in the preliminary studies reviewed here, materials were costed but other relevant costs, for instance cost of an additional day of sick leave[94], were not. Two trials performed a cost analysis, but not a true cost–effectiveness analysis[95].

Recommendations and the future

Most surgeons prefer the placement of a large mesh prosthesis in the preperitoneal space, by either a transabdominal or an extraperitoneal approach. The TEP technique is very promising, but its major drawback may be difficulty mastering it. The most popular method is the TAPP technique, which may also be easier to learn. While acceptable results can be achieved with this technique, there is a potential, although quite rare, for severe

Table 2 Randomized trials comparing open with laparoscopic hernia repair

Reference	Year	Technique	No. of patients	Power calculation	Main endpoint(s)	Postoperative pain	Costs	Return to activity (days)	Follow-up (months)	Recurrence (open *versus* laparoscopic)

TAPP, transabdominal preperitoneal laparoscopic repair; TEP, totally extraperitoneal laparoscopic repair complications such as bowel injury and obstruction. Even the small risk for such complications may not be acceptable for either patient or surgeon. Nevertheless, the TAPP approach might prove useful for its own set of indications and may be used in a complementary fashion to other methods.

Hitherto, randomized trials were small and designed to look at short-term outcome measures; they have not been able to detect differences in recurrence rates between operations. These studies were unequivocal about the advantage of laparoscopic herniorrhaphy over open repair in terms of faster rehabilitation. However, the most important question cannot yet be answered: are long-term recurrence rates for laparoscopic repairs better or worse than those for open repairs? Currently, there are four large trials (in order of initiation in Sweden, the Netherlands, UK and France) which have included or intend to include over 1000 patients each and these may eventually yield a definitive answer[96]. Some of these trials use the TEP approach for comparison and are conducting a cost-effectiveness analysis. As these studies are multicentred they may also prove more attractive in terms of general validity. Every general surgeon should be capable of performing laparoscopic inguinal hernia repair with acceptable rates of complications and recurrence. If not, we should question the world-wide introduction of this new technique.

We believe it is not yet appropriate to convert from a preferred individualized approach to a laparoscopic technique on a large scale. If such a conversion seems warranted in the future, the problems of the learning curve should not be regarded lightly if unacceptable rates of technical error and early recurrence are to be avoided. If necessary, training centres may be established to allow a controlled transition from conventional to laparoscopic hernia repair.

Division of the sphincter of Oddi for treatment of dysfunction associated with recurrent pancreatitis

J. TOOULI, V. DI FRANCESCO, G. SACCONE, J. KOLLIAS, A. SCHLOITHE and N. SHANKS

Gastrointestinal Surgical Unit, Department of Surgery, Flinders Medical Centre, Bedford Park, Adelaide, 5042 South Australia, Australia
Correspondence to: Professor J. Toouli

Increasing evidence suggests that motility disorders of the sphincter of Oddi may lead to episodes of recurrent pancreatitis in a small proportion of patients with the diagnosis of idiopathic recurrent pancreatitis. Over 10 years, 35 patients have been identified and treated for this condition. The aim of the study was to assess symptomatic outcome in these patients. Following the exclusion of common causes of pancreatitis the patients underwent sphincter of Oddi manometry. Patients with manometric abnormalities and three with normal manometric findings underwent treatment. Twenty-six patients with persistent symptoms underwent total division of the sphincter via open sphincteroplasty and septectomy. Patients were followed up according to symptoms and classed as having a cure, mild symptoms or no change. At a median follow-up of 24 (range 9–105) months, 15 of the 26 patients were cured, eight had only mild symptoms and three remained unchanged. In the majority of patients with a good clinical outcome, manometry had demonstrated sphincter of Oddi stenosis. Total division of the sphincter of Oddi is associated with good symptomatic outcome in patients with recurrent episodes of pancreatitis and documented sphincter of Oddi stenosis.

The cause of acute pancreatitis in the majority of patients is usually obvious; for most Western countries the major causes are alcohol consumption or gallstones[1,2]. However, in a significant number of patients the cause is unknown and when the episodes of pancreatitis recur a diagnosis is made of idiopathic recurrent pancreatitis[1–6]. The authors have previously described sphincter of Oddi motility disorders in a group of patients who presented with the clinical diagnosis of idiopathic recurrent pancreatitis, and postulated that sphincter of Oddi dysfunction may be one of the causes of this condition[5]. Sphincter of Oddi dysfunction has also been shown to be associated with recurrent biliary-type pain in some patients following cholecystectomy[7], and in those with a significant motility disturbance such as manometric stenosis, division of the sphincter was associated with relief of symptoms[8]. Other reports have also proposed an association between sphincter of Oddi abnormalities and the development of pancreatitis[9], and division of both the biliary and pancreatic sphincter of Oddi has been proposed as treatment for this condition[10]. The major difficulty in treating these patients has been the selection of patients who will best benefit from sphincter division.

Over 10 years ago the authors embarked on a prospective protocol which aimed to treat patients presenting with recurrent pancreatitis of unknown aetiology based on sphincter of Oddi manometric findings. The results of this policy have been recently reviewed and are presented in this report.

Patients and methods

Between January 1984 and December 1994, 35 consecutive patients with the clinical diagnosis of idiopathic recurrent pancreatitis were evaluated and treated. All patients had other causes of pancreatitis excluded by relevant investigations, done mainly by the referring physicians and reviewed by the authors. All patients had at least two documented episodes of pancreatitis with abnormally raised serum amylase values, and most had several documented episodes requiring inpatient hospital treatment.

Investigations

During the initial interview a detailed history was obtained and recorded on a standardized form designed to allow subsequent analysis of symptoms. Any provocative factors (such as specific foods, medications or alcohol) for initiating episodes of pancreatitis were identified and this information was used for subsequent treatment of the patient.

All patients underwent endoscopic retrograde cholangiopancreatography (ERCP) to eliminate a structural cause for the pancreatitis. In one patient with an intact gallbladder, bile was aspirated through the ERCP catheter and examined for the presence of microcrystals of cholesterol.

Management

Initially, patients were treated conservatively, aiming to avoid any identifiable provocative factors and to abstain totally from alcohol consumption. This did not prove difficult as in this series of patients the selection process excluded those with clinical evidence of alcohol dependence. Patients were followed clinically, initially at monthly intervals for 3 months and subsequently every 3 months. If symptoms improved or were tolerated, no further treatment was given. However, in the majority of patients the episodes of pancreatitis continued. These patients were next investigated by sphincter of Oddi manometry and a morphine–neostigmine provocation test.

Patients with a provisional diagnosis of sphincter of Oddi dysfunction were treated by division of the sphincter. Initially the division was confined to the biliary sphincter and performed endoscopically or by open operation. However, as time progressed and data from other studies in the authors' unit became available, it was decided that both the biliary and pancreatic components of the sphincter of Oddi should be divided by open transduodenal sphincteroplasty and septoplasty.

Manometry

The technique for sphincter of Oddi manometry has been described previously[7]. In brief, a triple-lumen manometry catheter was positioned across the sphincter of Oddi after its

---

Paper accepted 24 April 1996

introduction through the biopsy channel of a standard duodenoscope In patients in whom endoscopic sphincter of Oddi manometry was not possible, intraoperative recordings were attempted. Normal pressure values for the sphincter have been defined in previous studies[11]. Sphincter of Oddi dysfunction has been arbitrarily subdivided into two major categories of stenosis or dyskinesia based on the manometric findings. Sphincter of Oddi stenosis was diagnosed in patients with an abnormally raised basal pressure in excess of 40 mmHg. Sphincter of Oddi dyskinesia consisted of one or more motility disorders, such as paradoxical response to cholecystokinin-octapeptide administration, rapid contraction frequency or excess retrograde contractions[12].

Provocation test

The morphine–neostigmine provocation test has also been described previously[13]. A positive test was recorded when the pain was reproduced, as recorded by a linear analogue scale, by the administration of the drugs and there was an associated rise above the upper limit of normal in serum levels of amylase and liver transaminases

Sphincter division

Endoscopic sphincterotomy was performed by means of standard techniques The biliary sphincter was divided by a mixture of coagulation and cutting current with a Demling-type sphincterotome[14]

Sphincteroplasty and septectomy were performed under general anaesthesia and through a right subcostal transverse abdominal incision. The common bile duct was identified after division of adhesions usually present between the duodenum and gallbladder bed. A choledochotomy was performed and a 'step catheter' was passed down the bile duct and into the duodenum (*Fig. 1a*). The tip of the catheter could be palpated through the duodenal wall, thus facilitating placement of the duodenotomy. A small duodenotomy was made and the end of the step catheter grasped to bring the papilla into ready access. A routine sphincteroplasty was made of at least 2 cm in length so that the whole length of the biliary sphincter was divided (*Fig. 1b*) Mucosa-to-mucosa fine cat gut sutures were used for haemostasis and mucosal apposition. On completion of the biliary sphincteroplasty, the step catheter was elevated upwards to expose the opening of the pancreatic duct (*Fig 1c*) The manometry catheter was then inserted into the pancreatic duct to record from the pancreatic sphincter. In four patients the pancreatic sphincter was stenosed to such a degree at the time of the open operation that manometry was not possible. Cannulation could be achieved only by careful insertion of the finest of lacrimal probes. Under these circumstances it was considered justifiable to make the diagnosis of stenosis in these four patients. Once the pancreatic duct had been cannulated, the pancreatic sphincter was divided for a length that allowed free passage into the pancreatic duct (*Fig. 1d*). Often a gush of pancreatic juice escaped from the duct as the stenosed sphincter was finally divided. The septoplasty completed, the duodenum was then closed transversely

Follow-up

All patients were followed initially at monthly intervals for 3 months, then 3-monthly for 1 year, and subsequently yearly. Most patients were reviewed clinically by one of the authors; however, a number of patients had travelled from other Australian states for treatment and, after the initial follow-up, were reviewed by the referring doctor. The patients' records were then independently reviewed by two of the co-authors (V. di F. and J.K.). The patients were contacted by postal questionnaire and by telephone, and the results of treatment scored according to the following simple scale: 0, no symptoms; +, mild symptoms that are readily controlled by occasional analgesics and do not require medical or hospital treatment; NC, no change or worse.

Statistical analysis

Data were stored on a personal computer and analysed for presentation. Values are presented as median (range). Review of the patients' case notes was approved by the Flinders Medical Centre Clinical Investigations Committee.

Results

Patients

Most (30) patients were women and the median age was 39·5 (range 20–70) years. No patient had a history of heavy alcohol intake and only seven consumed any alcohol, reported at between one and seven regular drinks per week. There was no significant history of drug intake and ten smoked cigarettes. Six patients were nurses by profession; there was no evidence of analgesia abuse in this subgroup.

Previous medical history was non-contributory and all but one patient had had cholecystectomy prior to referral. It was difficult to determine the onset of pancreatitis in relation to the cholecystectomy in all patients. In at least eight patients documented pancreatitis had preceded cholecystectomy. In 20 patients cholecystectomy had been performed for stones, and the other 15 had had the operation in an effort to treat the pancreatitis. Eight patients had undergone endoscopic sphincterotomy at the time of referral. The sphincterotomy had not altered the episodes of pancreatitis.

Presenting symptoms

The most consistent symptom, which was reported by all patients, was recurrent pain. Patients were able to distinguish between recurrent major episodes of pain and more frequent minor episodes. The major episodes occurred at a median frequency of one per month (range of one every 2 days to one per year).

In half the patients the pain started in the epigastric region and radiated to either the back or right upper quadrant of the abdomen. In seven patients the pain originated in the right upper quadrant and radiated to the back, whereas in ten it started and did not radiate from the right upper quadrant. The pain was described as sharp and constant by 31 patients, with two describing it as cramping and two as burning.

Thirty-one patients experienced nausea in association with the pain and 19 had associated vomiting. The episodes of pain were related to food intake by seven patients and were reported to be aggravated by alcoholic drinks in seven and by taking codeine in nine. There was no significant temporal relationship to the onset of symptoms.

All the patients had required hospital admission for treatment of pancreatitis on at least one occasion, but most had had numerous admissions. The episodes of pancreatitis were usually mild, with pain lasting between 3 and 96 h. In the majority, pain was relieved by parenteral analgesics but in seven analgesics had no effect. Only two patients experienced severe pancreatitis with abnormal prognostic factors. The pancreatitis resolved with conservative treatment.

Investigations

All patients demonstrated abnormally raised serum amylase levels on at least two presentations with

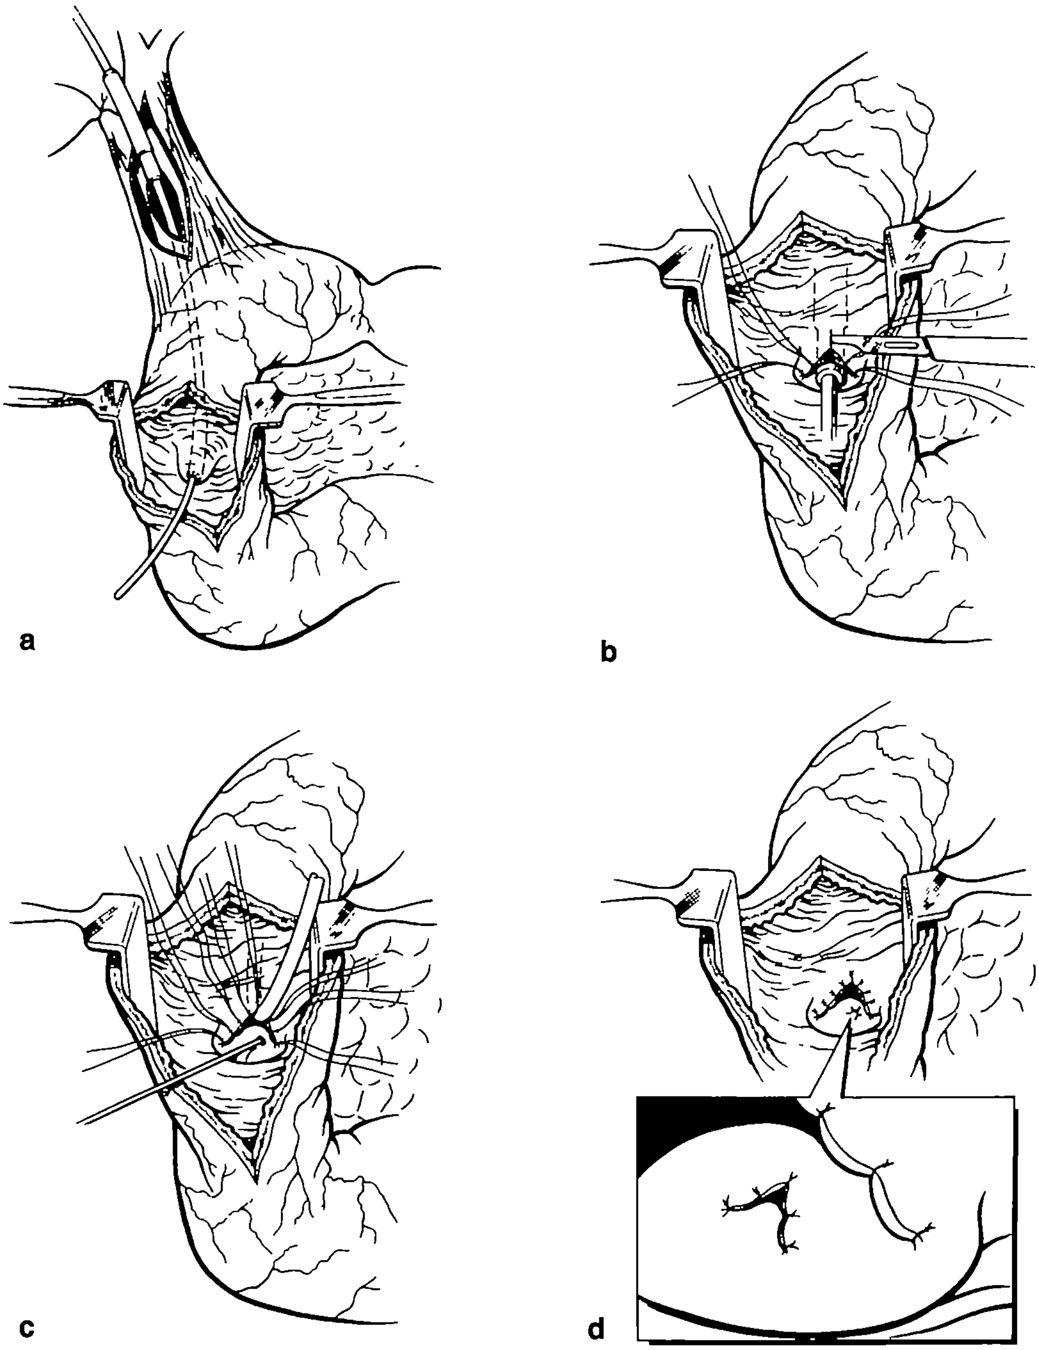

Fig. 1 Sphincteroplasty and septectomy. **a** A step catheter is introduced via a choledochotomy through the sphincter of Oddi and into the duodenum, thus facilitating identification of the papilla for precise positioning of the duodenotomy. **b** Biliary sphincteroplasty is performed and the edge is sutured together for mucosa-to-mucosa apposition. **c** The step catheter is elevated upwards to identify the pancreatic duct opening. A small catheter is then inserted into the pancreatic duct. **d** At completion of the operation on the sphincter, both the biliary and pancreatic parts have been divided completely

abdominal pain. In 25 pancreatitis was accompanied by abnormally raised levels of liver transaminases.

ERCP was attempted in 33 patients and was unsuccessful in two because of tight stenosis. In four of the 31 successful ERCPs the pancreatic duct was not adequately visualized. In the other 27 patients a good diagnostic pancreatogram was obtained. Initial ERCP had demonstrated slight ductal irregularities in only six patients. In a further four the bile duct was mildly dilated but in the remaining patients no abnormalities were observed. Overall, 14 of the 35 patients experienced abdominal pain during ERCP. One patient who had originally declined treatment by division of the sphincter was treated conservatively for 10 years. In this patient the initial ERCP showed no abnormalities. However, a repeat ERCP performed at the time of reassessment 10 years later demonstrated pancreatic duct changes consistent with chronic pancreatitis. Furthermore a number of calculi were present in a dilated pancreatic duct. There were no patients with pancreas divisum anomaly, as such cases had been excluded from this study.

Morphine–neostigmine test

This provocation test was performed in 17 patients and the results were abnormal in ten. All those with an abnormal test result exhibited abnormal manometric recordings. In addition, six of the other seven patients also displayed abnormal manometric findings, which may reflect the mechanism of selection of the patients for this series.

Manometry

Either endoscopic or intraoperative manometry was performed in 33 patients. Stenosis of the sphincter was recorded in 24 patients. In four of these patients the diagnosis of stenosis was made without the aid of manometry as the sphincter was too tight to allow insertion of the recording catheter. In these four patients an attempt to record sphincter pressures was made at open surgery. An inability to insert the manometry catheter through a tight sphincter at open operation was taken as consistent with the diagnosis of stenosis. In six patients manometry demonstrated dyskinesia and in the other three the manometric findings were normal.

Treatment

The initial form of therapy for this group of patients varied (*Fig. 2*), reflecting the changes in our understanding of this disorder. In seven patients prolonged medical treatment with antispasmotic drugs such as hyoscine was the initial treatment. In a further seven endoscopic sphincterotomy was performed. In two patients operative sphincteroplasty was carried out and in 19 the initial treatment was operative sphincteroplasty and septoplasty. A further seven underwent operative sphincteroplasty and septoplasty after failure of the initial therapy, resulting in 26 patients who had this procedure.

The operation was not associated with any significant complications. In particular there was no evidence of significant pancreatitis in any patient in the postoperative period, and no operative mortality. Two patients had mild hyperamylasaemia after operation, but this did not prolong their recovery.

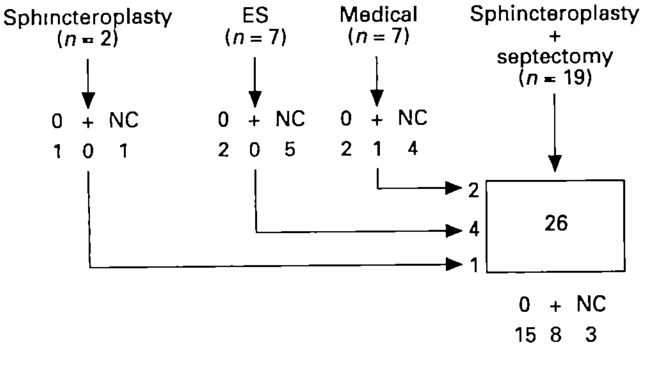

Fig. 2 Results of treatment for all 35 patients ES, endoscopic sphincterotomy; 0, cure; +, mild symptoms; NC, no change

Follow-up

The symptomatic follow-up of all patients is summarized in *Fig. 2*. In patients who did not initially have sphincteroplasty and septoplasty, the outcome was poor. In four of the seven patients having conservative therapy, there was no change in symptoms at a median of 24 (range 8–48) months of follow-up. Two of these patients were subsequently treated by sphincteroplasty and septoplasty. Five of the seven patients who had endoscopic sphincterotomy initially experienced no change in symptoms at a median of 12 (range 3–46) months after operation, and four of these subsequently underwent sphincteroplasty and septoplasty. Similarly, one of the two patients who had had operative sphincterotomy showed no improvement in symptoms at 23 months and then had a septoplasty.

The relationship between manometric diagnosis and initial medical therapy or biliary sphincterotomy is shown in *Table 1*. Sphincter of Oddi stenosis was associated with a poor outcome after medical therapy and for therapy directed only at the biliary component of the sphincter.

Sphincteroplasty and septoplasty were performed in 26 patients with median follow-up of 24 (range 9–105) months; 15 reported no further symptoms and eight had only mild symptoms that were treated by mild oral analgesics. None of these patients has required hospital treatment for pancreatitis. Therefore, 23 of the 26 patients who had sphincteroplasty and septectomy experienced clinically significant improvement from this procedure and none required subsequent medical treatment for recurrent pain. In three patients the operation did not alter the frequency or severity of symptoms (*Table 1*). Division of both the biliary and pancreatic sphincter is associated with a good outcome following the diagnosis of sphincter stenosis (*Table 1*).

Discussion

In this selected series of patients presenting with an initial diagnosis of idiopathic recurrent pancreatitis, sphincter of Oddi dysfunction was identified and total division of the sphincter led to a high probability of cure. A subjective assessment of outcome was made and thus a simple three-scale scoring system that did not require detailed recall was used. Grades of improvement or worsening of symptoms were not evaluated as these symptoms could not be assessed accurately. This series of patients was evaluated prospectively over the course of 10 years using a protocol that changed as accumulated data from other parallel studies pointed to the clinically most relevant form of therapy. The fact that it has taken 10 years to accumulate a series of only 35 patients reflects the relative rarity of this condition. It would be irrelevant to relate this value either to numbers of patients with pancreatitis treated in the same period or to those with dysfunction of the biliary sphincter of Oddi because most of the patients were tertiary referrals, often from a long distance from this institution, reflecting the authors' interest in this condition.

The presenting symptoms and signs were similar to those in previous series reported both by the authors[5] and by other investigators[6]. The clinical presentation is that of pancreatitis associated with no obvious cause. All except one of the present patients had had cholecystectomy performed previously in an attempt to remove the cause of recurrent pancreatitis; hence the question of passing cholesterol crystals from sludge in the gallbladder was not of relevance. In the one patient with an intact biliary tract the bile was examined for crystals, but these were not found. The association between passage of cholesterol crystals and pancreatitis has been well demonstrated in previous studies[15,16]. It might be postulated that the passage of crystals or microcalculi may have produced changes in the sphincter that are responsible for the recurrent episodes of pancreatitis, although there is no evidence to support this contention.

An interesting association with this disorder is the susceptibility of some patients to opiates and the induction of pancreatitis following their administration. This association was not universal for all patients, so that the morphine–neostigmine test has not proven to be a reliable investigation in selecting patients for treatment[13]. In this series of patients there was a higher association between the morphine–neostigmine test, manometric findings and outcome than has been found in other series[9]. However, this may reflect the highly selected nature of this group of patients and the mechanism by which they were screened and offered treatment. For most patients, inclusion in the series required that the majority of screening investigations be positive. A previous study of an unselected group of patients demonstrated that, although the morphine–neostigmine test was a useful screening investigation, it could not be used to select patients for treatment[13].

In a previous series of patients an association was demonstrated between sphincter of Oddi manometric abnormalities and idiopathic recurrent pancreatitis[5]. In particular, sphincter of Oddi stenosis as characterized by an abnormally raised basal pressure was noted[5]. This finding has been reaffirmed in the present series of patients, although the nature of their selection does not permit us to draw conclusions regarding the relative frequency of sphincter stenosis in patients with idiopathic recurrent pancreatitis. The cause of the stenosis is unknown. Histological examination was not performed routinely in these patients because of the difficulty of obtaining an adequate specimen safely; however, based on palpation and appearance at operation, the papilla was judged fibrotic rather than hypertrophic. Approximately one-third of the patients had previously undergone either endoscopic or operative biliary sphincterotomy, so it is possible that this procedure may have resulted in stenosis of the pancreatic sphincter. However, in most of these patients the pancreatitis had predated sphincterotomy, suggesting that, if it were a contributory factor, it would be the cause in only a small number of patients. Studies have shown that separate recording from the pancreatic sphincter in patients with recurrent pancreatitis will demonstrate manometric stenosis in the absence of stenosis of the biliary sphincter[17,18].

The aetiology of sphincter of Oddi dysfunction is unknown. One potential cause is the continual and intermittent passage of gallstones through the sphincter, which may cause trauma resulting in inflammatory changes and fibrotic repair. However, this cannot have been the cause in all of the present patients as 15 did not have gallstones. Possibly this condition may reflect a spontaneous motility disorder of the sphincter similar to other such disorders of the gastrointestinal tract. Like other motility disorders and biliary sphincter of Oddi dysfunction, it is more common in women. However, an association or causal relationship with female reproductive hormones has not been demonstrated.

Treatment of sphincter of Oddi dysfunction which involves only the biliary sphincter is by endoscopic sphincterotomy. In a prospective series of patients it was demonstrated that endoscopic division of the sphincter in those with manometrically demonstrated stenosis resulted in a high rate of cure[8]. In a previous series[10] it had also been demonstrated that the operation of sphincteroplasty and pancreatic duct septoplasty was associated with pain relief in a subgroup of patients who presented with recurrent pancreatitis or pancreatic pain. However, in both these earlier series the patient population was heterogeneous and included some with an alcohol aetiology for the pancreatitis and others who were dependent on narcotics. Hence, although the outcome was good for a majority of patients, it was not clear how they could be effectively selected for operation.

The results of the present series demonstrate the value of sphincter of Oddi manometry for the selection of patients to undergo total division of the sphincter by sphincteroplasty and septectomy. An observable manometric stenosis is associated with a high rate of cure from recurrent pancreatitis following sphincter division. In this series the sphincter was divided by open operation and the authors were not tempted to explore the possibility of endoscopic pancreatic sphincter division. Sporadic reports have appeared recently of this procedure[6,8,19–21]. It is crucial, whichever approach is used, that the pancreatic duct be left wide open at the end of the procedure as oedema at the site of the operation may produce duct obstruction and the possibility of a further episode of pancreatitis in the post-procedure period.

Sphincter of Oddi dysfunction as a cause of idiopathic recurrent pancreatitis is an uncommon but debilitating condition. When suspected, the diagnosis is readily made by endoscopic sphincter of Oddi manometry. If a stenosis is recorded, division of both the pancreatic and the biliary sphincter has been shown to be associated with good results on long-term follow-up.

Case report

Pancreatitis in childhood associated with villous adenoma of the ampulla of Vater

M. ARIF MATEEN KHAN,
D. M. THOMAS* and E. R. HOWARD
*Departments of Paediatric Surgery and *Histopathology, King's College Hospital, Denmark Hill, London SE5 9RS, UK*
Correspondence to: Professor E. R. Howard

Pancreatitis in childhood is rare[1] and, unlike most adult disease, is usually attributable to a specific lesion. A unique association of relapsing pancreatitis with an adenoma of the ampulla of Vater is reported.

Case report

A 14-year-old boy presented with a 10-year history of recurrent central abdominal pain. Two estimations of serum amylase were found to be increased. Endoscopic retrograde cholangiopancreatography revealed a dilated pancreatic duct with obstruction in the region of the head of the pancreas. In view of the recurrent nature of the symptoms and the obstruction of the pancreatic duct, pancreatoduodenectomy was undertaken. There were no postoperative complications, and no further attacks of pancreatitis have occurred since operation.

On macroscopic examination of the specimen, the ampulla was mildly enlarged and firm and its covering mucosa appeared normal. The pancreas was firm; the ducts appeared slightly dilated and contained mucinous plugs. Microscopy showed an exophytic, tubulovillous adenoma within the ampulla, 5 mm in diameter with mild epithelial dysplasia. Chronic inflammation was present throughout the pancreas (*Fig. 1*).

Discussion

Pancreatic duct obstruction in association with pancreatitis in children has been described with helminthic infestation, gastric duplication cysts and anomalous drainage of the pancreatic duct into the fourth part of the duodenum, common pancreatico–biliary channels and annular pancreas[1]. Because of the rarity of these conditions, diagnosis is often delayed as it was in the present report. Dabadie *et al.*[2] reported a case of acute pancreatitis caused by the impaction of a paper clip in the ampulla of a 14-month-old child. A large papillomatous tumour with a weight of 750 g has been described arising within the bile duct of a 4-year-old child, but this tumour was not associated with pancreatitis[3].

In adults adenomas are the commonest benign tumours of the extrahepatic biliary tree, and approximately half are situated near the ampulla of Vater. Patients commonly present with right upper quadrant pain and jaundice. These tumours may contain areas of dysplasia and carcinoma, and these features have been reported previously in three patients[4]. Furthermore, a recent study from Japan demonstrated carcinoembryonic antigen and carbohydrate antigen 19-9 in ampullary adenomas with mild-to-moderate dysplasia, an appearance which is also seen in colorectal carcinoma[5]. Surgical management therefore includes complete excision to ensure against later malignant transformation, as in the present case.

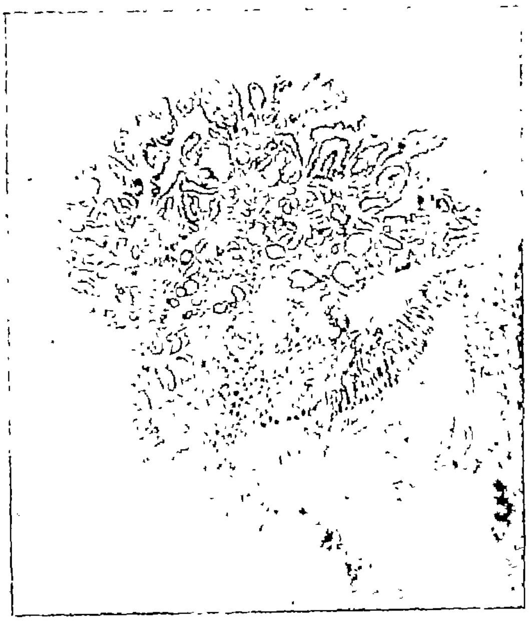

Fig. 1 Histological section of a tubulovillous adenoma, 5 mm in diameter, arising within the ampulla of Vater. The epithelium was mildly dysplastic

The spleen may be removed by a laparoscopic technique, although the benefits and associated morbidity of this approach are unknown. This study reports a series of 28 consecutive patients (15 women; median age 39 (range 17–84) years) considered for laparoscopic splenectomy, because of idiopathic thrombocytopenia in 14, human immunodeficiency virus-related thrombocytopenia in seven, autoimmune haemolytic anaemia in four, lymphoma in two and chronic lymphocytic leukaemia in one. In 23 cases dissection was completed laparoscopically, with the patient in the right lateral position, using a four-cannula technique. Vascular isolation was achieved with an Endo-GIA (powered vascular linear stapler). The spleen was removed by morselation within a retrieval bag (18 patients) or via either a Pfannenstiel or subcostal incision (five). The last 14 procedures have all been completed successfully in a mean operating time of 105 min with discharge from hospital within a median of 3 days. One patient developed a clinically apparent deep venous thrombosis 23 days after operation, for which he required readmission. Elective laparoscopic splenectomy is a feasible although technically demanding operation which may be performed safely and without associated mortality by surgeons experienced in laparoscopic techniques.

The significant benefits of laparoscopic surgery may not be realized by intra-abdominal operations that require prolonged and difficult dissection or gastrointestinal anastomosis[1–3]. Although the spleen is a relatively inaccessible organ with a large and fragile blood supply, its peritoneal attachments are easily defined and, once mobilized, it has a single vascular pedicle. This makes the spleen a suitable organ for laparoscopic surgery[4–10] from which a rapid recovery might be expected. The three major obstacles to laparoscopic splenectomy are: access, vascular isolation and retrieval of the organ. Each of these has been overcome by the technique described below.

Patients and methods

In a 40-month period, from February 1992, 28 patients (15 women) of median age 39 (range 17–84) years were referred for splenectomy. Fourteen patients had idiopathic thrombocytopenia, seven had thrombocytopenia related to human immunodeficiency virus (HIV) infection, four had autoimmune haemolytic anaemia, two had malignant lymphoma and one had chronic lymphocytic leukaemia. Laparoscopy was performed in all patients except two where there was massive splenomegaly that would have precluded retrieval of the dissected spleen

Operative technique

Preparation All patients with HIV-related thrombocytopenia received platelet transfusions before surgery. Those with autoimmune haemolytic anaemia and idiopathic thrombocytopenia were given platelet transfusions following division of the splenic hilum. All patients received Pneumovax (Pasteur Merieux, Maidenhead, UK) before operation and prophylactic antibiotics were given during the operative period.

Technique. The patient is placed with the trunk rotated towards the right lateral position (*Fig. 1a*), slightly head up and with a 10° break in the table. Excessive forward rotation, which causes the spleen to fall forwards, can impair access particularly with larger spleens and so is avoided. The surgeon and assistant (camera operator) stand to the right of the patient. A 1-cm supraumbilical incision is made and carbon dioxide insufflation is performed through a Veress needle to an inflation pressure of 14 mmHg. A 10-mm disposable cannula is inserted and laparoscopy is performed with a 0° telescope. The anterior and posterior adhesions to the spleen are assessed, and then three 5-mm cannulas are inserted in the epigastrium, mid-clavicular line and anterior axillary line – the mirror image of positions used in laparoscopic cholecystectomy. Attachments of the splenic flexure of the colon occasionally impede the positioning of the lateral cannula and access of the lienorenal ligament. If so, the splenic flexure is mobilized before insertion of the most lateral cannula. A diathermy hook is placed in the lateral cannula, a suction irrigator in the central cannula and an atraumatic grasper in the epigastric cannula.

The posterior edge of the spleen is elevated and held in this position by the assistant. The lienorenal ligament is divided by means of diathermy, allowing the spleen to become increasingly mobile. Exposure of the lienorenal ligament in the last four patients of the series has been greatly improved by using a 10-mm epigastric cannula (in place of the 5-mm cannula), to provide access for a 'Fan' retractor (AutoSuture, Ascot, UK) during this dissection. It is important to continue this dissection as far superiorly as possible, as high posterior adhesions to the diaphragm are difficult to divide at a later stage. The hilar vessels and the tail of the pancreas come into view and are protected The spleen is placed back in its bed and the anterior edge is elevated. In most cases no adhesions are present, but some dissection may be required if there are non-anatomical adhesions to the stomach. Omental adhesions, often present at the lower splenic pole, are not suitable for diathermy as they may contain sizeable vessels. They should be divided between clips if they are impeding elevation of the spleen, or incorporated within the jaws of the stapler during division of the hilar vessels. Great care is taken during the dissection not to breach the splenic capsule as this may cause troublesome bleeding and the risk of splenic autotransplantation. Minor bleeding is controlled by suction irrigation and diathermy. Secure haemostasis is achieved as the hilum is cross-stapled and this remains the primary objective of the dissection at all times.

By placing a retractor on each side of the hilar structures, the spleen can be elevated (*Fig. 1a*) and the thickness of the hilum estimated Although the best angle of approach for the stapler to

Paper accepted 23 April 1996

the hilum is most often via the mid-clavicular cannula, in some cases the lateral cannula is more appropriate. The chosen 5-mm cannula is replaced with one of 15 mm and a powered vascular linear stapler (Endo-GIA60; AutoSuture) is inserted, opened and carefully positioned across the hilum. The instrument can be closed without firing so that it can be repositioned without difficulty. Once positioned, abutting the spleen and encompassing the hilar vessels (*Fig. 1b*), the stapler is fired, opened and carefully withdrawn. The spleen is now attached only by the short gastric vessels and is highly mobile. A second and third firing of the stapler may be required to complete the separation of the spleen. A shorter 30-mm stapler has been tried but required more firings and was no easier to manipulate into position.

A large retrieval bag is inserted via the 15-mm cannula and the spleen is manipulated into it. Saline irrigation is performed and the splenic bed, omentum and mesentery are examined for splenunculi. None was found in this series. The bag is withdrawn and the spleen is removed piecemeal after morselation with sponge holding forceps. In cases where the spleen is required intact for histological examination, or if it is too large to be placed in a retrieval bag, a small Pfannenstiel incision is made to retrieve the organ. A suction drain is placed in the splenic bed through the most lateral cannula. Bupivacaine 0·5 per cent with adrenaline 1:200000 is infiltrated into the wounds (total volume 20 ml). The 15-mm cannula site is closed in layers with 2/0 polyglactin and subcuticular 3/0 polyglactin to the skin. The 5-mm incisions are closed with sterile skin closure strips.

Postoperative care. The patient is allowed to eat and drink on recovery from the anaesthetic, usually on the evening of surgery. Completion of splenectomy was assessed at operation and by the patient's clinical course after operation. Isotope scans have not been required to detect residual splenunculi.

Results

In the two patients with lymphoma there was massive splenomegaly; the retrieved spleen weighed 1·5 and 2·5 kg. The patient with chronic lymphocytic leukaemia also had a spleen weighing more than 1 kg which was not suitable for laparoscopic dissection. These organs would have been irretrievable even if the laparoscopic dissection had been successful; two of these patients underwent open surgery without laparoscopy. One patient with autoimmune haemolytic anaemia had undergone previous transperitoneal aortic aneurysm surgery and, although laparoscopy was safely performed, dense adhesions forced early conversion to open surgery.

Laparoscopic evaluation was performed in 26 patients and splenectomy was attempted in 25. The spleen was successfully mobilized and separated in 23 patients. In one case the hilar vessels were damaged by accidental injury with the Endo-GIA stapler and subsequent bleeding forced conversion. The second patient, who had acquired immune deficiency syndrome (AIDS), proved to have a markedly thickened hilum which could not be safely thinned to allow application of the stapler. In the remaining 23 patients the operation was completed entirely laparoscopically in 18 and open retrieval was performed in five cases, three for suspected lymphoma and two because the spleen was too large to fit into the retrieval bag.

Two patients in the first half of the series required early reoperation for bleeding. In the first, a postoperative heparin infusion (to protect a prosthetic mitral valve) was associated with bleeding from a small artery close to the staple line. In the second patient with AIDS, hepatitis B and C, and related hepatic cirrhosis, the site of bleeding was not identified but a good recovery was made following evacuation of the haematoma.

There were no infective complications following surgery. One patient, admitted 23 days after surgery with a proven pulmonary embolus, was treated by anticoagulation. There were no other perioperative complications.

The mean time from induction of anaesthetic to transfer to the recovery area was 137 (range 40–260) min, falling from 175 min for the first 11 operations to 105 min for the last 14. Uncomplicated patients (those with idiopathic thrombocytopenia and autoimmune haemolytic anaemia) treated entirely laparoscopically were discharged a median of 3 (range 1–5) days after operation and those with HIV infection or AIDS with more complex associated problems left hospital after 5 (range 2–8) days.

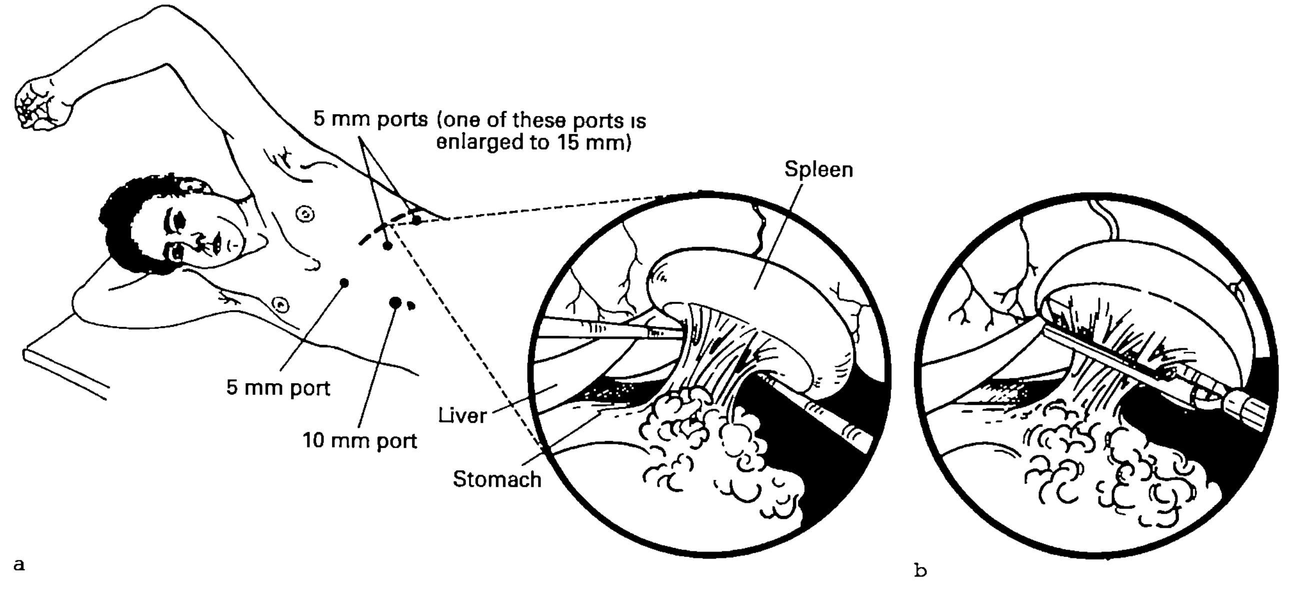

Fig. 1 a Port-site positions with the patient in the semi right-lateral position, allowing mobilization and elevation of the spleen (inset). b The powered vascular linear stapler is placed across the hilum of the spleen, closed and fired

Patients who required open retrieval were discharged a median of 6 (range 2–13) days after surgery. There was no postoperative mortality.

Discussion

The most common indication for elective splenectomy is thrombocytopenia[11–15], which may be HIV related[16–19]. Mortality has been reported following splenectomy in patients with AIDS[20]. A secondary concern during AIDS-related surgery is exposure of the surgeon to the patient's body fluids[21]. Both the patient and the surgical team may therefore benefit from a minimal access approach.

Using this technique, the authors have found laparoscopic splenectomy to be a technically feasible operation which may be performed within a reasonable operating time. This approach, when successfully completed, has led to a reduction in hospital stay, even in patients with AIDS. The benefits, in terms of reduction of hospital stay, are similar to those achieved by laparoscopic cholecystectomy[22].

Problems associated with this technique have been related to its development and occurred in the first half of the series. In particular, the procedure requires safe handling techniques for the spleen using laparoscopic instruments and the use of the powered vascular linear stapler. Considerable skill is required in the safe elevation and mobilization of the spleen, particularly when it is large. Preoperative splenic artery embolization and early clipping of the splenic artery via a posterior gastric approach have been advocated to reduce operative blood loss[23,24]. The technique described here has overcome the problem of blood loss without the need to utilize either of these techniques.

Spleens that are bigger than the largest retrieval bag, or that are required whole for pathological examination, require an open retrieval which can be achieved through a Pfannenstiel incision. The present results with this technique compare well with others[25]. Although single-handed mobilization of the spleen through a Pfannenstiel incision has been described by Kusminsky *et al.*[26], a procedure that has obvious advantages for patients with larger spleens, this was not attempted in any of the present patients.

Elective splenectomy is a relatively uncommon procedure which can be performed laparoscopically, although this requires considerable technical expertise. The authors would recommend that this procedure be performed in a limited number of specialist centres to maximize the experience gained by laparoscopic surgeons. This technique is reliable, associated with low morbidity and can be performed in an acceptable time.

In conclusion, laparoscopic splenectomy offers a considerable reduction in postoperative morbidity, similar to that associated with laparoscopic cholecystectomy. The operation may be performed with the minimum of specialist instrumentation by appropriately trained laparoscopic surgeons.

Changing management of pyogenic liver abscess

R. RINTOUL, M. G. O'RIORDAIN, I. F. LAURENSON*, J. L. CROSBIE,
P. L. ALLAN† and O. J. GARDEN

*University Departments of Surgery, *Medical Microbiology and †Radiology, The Royal Infirmary, Edinburgh EH3 9YW, UK*
Correspondence to. Mr O. J. Garden

The case records of 23 patients who presented over a 5-year period with a diagnosis of pyogenic liver abscess were reviewed. Ascending cholangitis was implicated in nine cases, seven of which were associated with underlying malignancy. Haematogenous spread via the portal route accounted for five cases. Primary treatment included percutaneous abscess drainage in 15 patients. Whereas nine of the 11 patients with benign underlying pathology were managed successfully, the four with malignant biliary obstruction did not survive. Only one of the 23 patients who presented with hepatic abscess required surgical intervention. Percutaneous abscess drainage combined with appropriate antibiotic therapy is an effective means of managing hepatic abscess, but there remains a substantial overall mortality rate resulting from the increasing incidence of malignant biliary obstruction as a cause of this condition.

The incidence of pyogenic liver abscess has remained relatively constant during this century despite earlier diagnosis and treatment of underlying causes and more aggressive antibiotic therapy[1–3]. In recent years the decrease in cases resulting from haematogenous spread from infective foci has been mirrored by an increase in cases secondary to hepatobiliary pathology[1,3]. In particular, advances in the management of hepatobiliary malignancy have led to increased survival times and pyogenic liver abscess is more commonly being seen as a complication following percutaneous or endoscopic management of biliary obstruction[4]. In the past, traditional treatment of liver abscess comprised antibiotic therapy and surgical drainage but, more recently, the role of percutaneous drainage in the management of this condition has been emphasized[5–8].

A review was carried out of the present authors' experience of pyogenic liver abscess to examine the aetiology and to determine the effectiveness of the management policy of percutaneous drainage as the mainstay of treatment for such patients.

Patients and methods

The case records of patients with a discharge diagnosis of pyogenic liver abscess who were admitted to the hepatobiliary surgical unit of Edinburgh Royal Infirmary between January 1989 and December 1993 were reviewed. A computerized search of appropriate discharge diagnosis codes was made and cross-referenced with a similar search of microbiological records. Twenty-three patients were identified for this 5-year period, of whom 16 had been transferred from other centres. Patients who had been admitted to the unit with cholangitis and occlusion of stents were not included in the study if, at the time of repeat endoscopic retrograde cholangiography, small abscesses were shown to be communicating with the biliary tree.

Diagnosis was made by a combination of clinical findings, visualization of abscess by ultrasonography or computed tomography (CT), aspiration of purulent material from the radiological abnormality and post-mortem examination. Specimens were collected in a sterile container and sent for immediate aerobic and anaerobic culture. Patients with amoebic abscess were excluded. Using a standard pro forma, patient demographic details, presenting symptoms and signs, haematological and biochemical results, microbiological findings, diagnostic method findings, abscess characteristics, aetiology, treatment and final outcome were documented.

Before microbiological identification from blood and/or drain cultures, broad-spectrum antibiotics were often administered. These were modified when sensitivities became known. Percutaneous drainage of collections larger than 5 cm was normally undertaken using ultrasonography for initial guidance. Puncture was done using a 16-G needle–catheter assembly followed by fluoroscopy for the insertion and manipulation of appropriate drains using a Seldinger technique. Smaller collections, or those where access was difficult, were punctured initially with a 22-G needle through which a 0·18-inch guidewire (Neff Set; Cooks, Letchworth, UK) was passed. Subsequent exchanges allowed placement of a 0·89- or 0·97-mm guidewire, along which a drain of appropriate size was inserted. Percutaneous aspiration alone was used when small multiple abscesses were demonstrated. If biliary obstruction was demonstrated, percutaneous or endoscopic drainage of the biliary tree was subsequently undertaken. Drains were left in place until resolution of symptoms and signs, until drainage ceased or until the abscess was shown to have resolved on scanning and/or by tubography. Surgical drainage or hepatic resection was reserved for chronic hepatic sepsis unresponsive to non-operative treatment.

Results

Of the 23 patients, 17 were men. The median age was 62 (range 23–80) years. Fever, abdominal pain and tenderness were the most prevalent symptoms and signs at the time of diagnosis (*Table 1*). The duration of symptoms before hospital admission ranged from 1 day to 6 months. For the 20 patients who had pyogenic liver abscess at the time of hospitalization, the median delay to diagnosis was 4 (range 1–21) days.

Significant haematological and biochemical abnormalities are presented in *Table 2*. Serum albumin concentration was measured in 17 patients and found to be below the normal range (less than 35 g/l) in 16. C-reactive protein levels were raised in all nine patients in whom it was measured (median 10·3 (range 3·4–20·8) mg/dl; normal value less than 1·0 mg/dl).

All 23 patients underwent ultrasonography or CT. Ultrasonography was used in 21 patients and failed to detect abscesses in only two, in whom their presence was suspected clinically. Of these two patients, an abscess was subsequently found by CT in one and at autopsy in the

other. CT was used as the first-line imaging investigation in two patients, and an abscess was seen on both occasions. Biliary dilatation was not a prominent feature on either ultrasonography or CT in patients with known or suspected biliary pathology.

Abscess morphology and microbiology

Single abscesses were found in eight patients and multiple abscesses in 15. Abscesses were restricted to the right lobe in 17 cases and occurred in both lobes in six. There were no cases of the left lobe being involved alone. The abscess ranged in size from 1 to 16 cm.

Sixteen of the 23 patients had positive blood cultures. Of the 21 patients who had pus aspirated or drained from abscesses, 16 had positive cultures. Overall, of the 20 patients with positive cultures, 11 were polymicrobial; only two of these patients had received antibiotics before admission to hospital. None of the three patients with negative cultures had taken antibiotics before hospital admission. The most commonly identified groups of organisms were Enterobacteriaceae, *Streptococcus milleri* and enterococci (*Table 3*). Only three of 37 isolates were anaerobes.

Aetiology

A cause for abscess formation was identified in 20 patients. Ascending cholangitis was implicated in nine cases, seven of which were associated with malignancy. Overall, hepatic causes accounted for three abscesses and haematogenous spread via the portal route for five. No cause was found in three cases (*Table 4*).

Management

All 23 patients received broad-spectrum antibiotics. In four patients this comprised the only medical treatment. Fifteen patients underwent percutaneous abscess drainage. In the others the only intervention was decompression of the biliary tree, one by percutaneous drainage, the other by endoscopic drainage. One patient was treated by operation. In one patient the diagnosis was made as an incidental finding at autopsy, the cause of death having been shown to be due to uncontrolled sepsis secondary to suppurative cholecystitis.

Medical treatment

Of the four patients treated with antibiotics alone, three had undergone diagnostic percutaneous needle aspiration of the abscess. Diagnostic aspiration was chosen in these cases rather than percutaneous abscess drainage because of the multiplicity of small lesions unsuitable for drain insertion. In no case was there clinical or radiological evidence of obstruction of the biliary tree. The two patients with underlying benign pathology (gallstones, one; chronic pancreatitis, one) survived whereas the two with carcinomatosis died in hospital. The patient with gallstones subsequently underwent open cholecystectomy on a second admission and was found to have common bile duct stones which were dealt with by exploration of the common duct.

Biliary tree decompression

Two of the patients who had developed multiple abscesses as a result of malignant obstruction required biliary decompression in addition to antibiotic therapy. One patient underwent initial percutaneous biliary drainage followed by internalization of the stent and the other had endoscopic placement of a biliary stent. In both instances, the abscesses resolved without the need for direct abscess drainage.

Percutaneous abscess drainage

Fifteen of the 23 patients underwent percutaneous abscess drainage (PAD) as the primary treatment. Of this group of 15, four had underlying malignancy and 11 had a benign pathology. There was only one postprocedural complication, a self-terminating episode of haemorrhage into the percutaneously placed drain. All four patients with malignant pathology had some degree of abscess resolution with drainage and antibiotic therapy but, despite repeated attempts to improve biliary drainage by endoscopic or percutaneous means, all four developed recurrent abscesses and died from a combination of sepsis and progression of tumour within 1 year of initial presentation.

Of the 11 patients with abscesses due to a benign cause, nine had complete resolution of the abscess by PAD and antibiotic therapy. Of the two patients who developed recurrent abscess formation, one died from chronic granulomatous disease and the other required a right hepatectomy to remove an inflammatory pseudotumour. In this latter patient, the abscess recurred several months after apparently successful percutaneous drainage. CT had demonstrated an inflammatory mass in the posterior sector of the liver which did not settle after repeat percutaneous drainage. A further patient in this group with a benign cause subsequently underwent laparoscopic cholecystectomy, the previously resolved abscess having been demonstrated to communicate with the gallbladder.

Surgical drainage

One patient who had developed a hepatic abscess secondary to obstructing pancreatic carcinoma underwent surgical drainage of the abscess and decompression of the biliary tree by means of hepaticojejunostomy. Previous attempts at endoscopic biliary stenting before referral had been unsuccessful. The hepatic abscess resolved and the patient was successfully discharged from hospital.

Outcome

Eight patients died in hospital. Only three of the nine patients with underlying malignancy were successfully discharged from hospital. There were two deaths in the 14 patients with non-malignant disease. In one of these patients the underlying pathology was chronic granulomatous disease. The other death was a result of overwhelming sepsis secondary to suppurative cholecystitis. In this patient, who died within 24 h of admission, pyogenic liver abscess was an incidental finding at autopsy.

Discussion

The mean age of patients with pyogenic liver abscess has shown a progressive rise over the past few decades[1,5,6]. In this study the median age of patients at presentation was 62 years. This trend is primarily a reflection of the changing aetiology of pyogenic liver abscess, as in the past haematogenous spread from distant infective foci was common[1]. Several other recent series mirror the present experience in demonstrating that ascending cholangitis as a result of biliary obstruction primarily due to malignant disease is now the main cause of liver abscess in the non-immunosuppressed patient[5,7–9].

CT is advocated as being more sensitive than ultrasonography[10], but the latter is still the first-line investigation in the authors' centre, even though it is accepted that this technique is operator dependent and may not adequately exclude the presence of other abscesses. Although certain areas of the liver may be difficult to visualize by ultrasonography and results can be limited by technical factors[10], ultrasonography is undoubtedly cheaper and does not use ionizing radiation. It also enables real-time guidance of drainage procedure in the majority of cases. The ready availabiliy of ultrasonography also assists in decreasing the delay in diagnosis. None the less, CT was useful in one patient in the present study when ultrasonography failed to detect obvious hepatic sepsis, and it may be useful in assisting to differentiate malignant from benign abscess formation. Fine-needle aspiration may be needed to clarify the diagnosis in some patients, but some authors have advocated isotope scanning, cholangiography and selective angiography[3,11]. These investigative modalities are largely redundant and were not used in any patient in the present series. They have been superseded by non-invasive imaging techniques such as ultrasonography, CT and, more recently, magnetic resonance imaging.

Enterobacteriaceae, enterococci, *Streptococcus milleri* and anaerobes are common gastrointestinal tract isolates, and were all identified in the liver abscesses in the present series. Whereas the pattern of aerobic infection is similar to that of other reported series, the relatively low incidence of anaerobic infection compared with that in other series may be a reflection of specimen collection techniques[3,11]. Fine-needle aspiration with rapid handling and anaerobic incubation is important for the isolation of anaerobes. Minimum delay between specimen collection and anaerobic incubation is necessary to optimize the recovery of anaerobes. In this series cultures from 11 of 20 patients were polymicrobial and this too accords with a gastrointestinal origin.

Currently both percutaneous needle aspiration and PAD in conjunction with antibiotics are advocated as alternatives to surgery in the management of pyogenic liver abscess when immediate surgery is not required to deal with coexistent intra-abdominal pathology[7,12,13]. Percutaneous therapy offers a low-risk approach to often critically ill patients and achieves effective drainage without the need for general anaesthesia and surgery. There is current debate in the literature over the comparative efficacies of non-surgical treatment[5,7,8,11,14,15]. Though a combination of antibiotic therapy and PAD is thought to be more effective, there are to date no controlled trials comparing this with antibiotic therapy and diagnostic fine-needle aspiration. The latter technique provides material for both histological and bacteriological analysis when there is doubt regarding the aetiology of the abscess. Irrespective of whether PAD or percutaneous needle aspiration was undertaken in the present series, patients with underlying malignancy fared badly.

Only one patient underwent surgical drainage of an abscess as a primary procedure, whereas another, whose abscess recurred despite repeated PAD, underwent right hepatectomy to remove an inflammatory pseudotumour evident on CT. The proportion of patients in the present series who underwent immediate surgery was low compared with that in other reports[5,6]. When percutaneous drainage was initially introduced for the management of hepatic abscess, morbidity and failure rates were equal or greater to those obtained at surgery[5,6], but with increasing experience failure rates of PAD appear to have fallen[16]. Although percutaneous drainage failed in six of 15 patients in the present series, this was undoubtedly biased by the high proportion with underlying malignancy who were not obvious candidates for surgical intervention.

PAD combined with appropriate antibiotic therapy appears to be the treatment of choice, given its higher success and low complication rates. The procedural complication rate of one in 15 compares favourably with published complication rates of 4–20 per cent[5,12]. There were no deaths directly attributable to the drainage procedure in the present series and clearly a percutaneous approach is more appropriate for patients with extensive carcinomatosis in whom cure is unlikely. However, in this latter group, effective biliary drainage is as important as abscess drainage if sepsis is to be adequately controlled. This was emphasized by the two patients with pyogenic liver abscess secondary to malignant obstruction of the biliary tree in whom sepsis resolved with a combination of biliary decompression and antibiotic therapy alone. On the other hand, four other patients who underwent direct abscess drainage but had unrelieved biliary obstruction died in hospital.

The mortality rate of two of 14 patients with non-malignant disease, similar to that of other recent series[5,7,12] demonstrates that the prognosis for a patient with pyogenic liver abscess has much improved over the past 15 years. This appears to be due to a combination of more rapid diagnosis as a result of improved radiological imaging, more effective antibiotic therapy and the development of percutaneous drainage procedures. The prognosis, however, for patients with pyogenic liver abscess with underlying hepatobiliary malignancy remains poor and will continue to provide a challenge in the future.

Recurrence of hepatocellular carcinoma after surgery

J. YAMAMOTO, T. KOSUGE, T. TAKAYAMA, K. SHIMADA, S. YAMASAKI, H. OZAKI, N. YAMAGUCHI* and M. MAKUUCHI†

*Department of Surgery, National Cancer Centre Hospital, *Epidemiology Division, National Cancer Centre Research Institute and †Second Department of Surgery, Tokyo University School of Medicine, Tokyo, Japan*
Correspondence to: Dr J. Yamamoto, Department of Surgery, National Cancer Centre Hospital, 5-1-1 Tsukiji, Chuo-ku, Tokyo 104, Japan

A total of 386 patients who underwent complete resection of hepatocellular carcinoma over an 8-year period were assessed retrospectively for tumour recurrence. Some 219 (56·7 per cent) of the patients developed recurrence. Patients with a greater degree of cirrhosis showed a longer interval to recurrence; the median (range) interval until recurrence was 7·9 (1·8–84·2) months in patients with a normal liver, 13·4 (2·0–79·5) months in those with chronic hepatitis and 16·7 (1·5–73·1) months in those with cirrhosis. Intrahepatic recurrence was observed more frequently in either the same (26·4 per cent) or the adjacent (24·8 per cent) Healey segment than in the lobe contralateral to the primary tumour (17·8 per cent). The presence of portal venous invasion and/or intrahepatic metastasis, underlying liver cirrhosis and perioperative blood transfusion were determined to be independent predictors of recurrence by multivariate analysis. Because intrahepatic spread of hepatocellular carcinoma occurs in a segment-by-segment manner, surgeons should use an anatomically wide resection within the hepatic functional reserve.

Recent advances in surgical techniques for liver resection have made operation a safe and effective treatment for hepatocellular carcinoma (HCC), and the survival rate of patients with hepatoma after curvative resection has been reported to exceed 50 per cent[1]. However, even if the resection is curative, recurrence is frequently encountered, especially in the residual liver, within a relatively short period after operation[2–7]. Early spread via the portal venous system as well as possible multicentric carcinogenesis of HCC, especially in the cirrhotic liver, limits the potential for surgical cure of hepatoma[8]. This study examined patients who underwent complete resection for HCC over an 8-year period and assessed post-resection recurrence to determine a rational surgical protocol for the disease.

Patients and methods

Between 1984 and 1991, 492 patients underwent primary hepatic resection for HCC at the National Cancer Centre Hospital in Tokyo. Twelve patients (2·4 per cent) died within 1 month of surgery or during the initial hospital stay. In 94 patients (19·1 per cent) the resection was incomplete. Of these, 23 patients had exposed non-encapsulated tumours, 11 had ruptured encapsulated tumours, 18 had a positive surgical margin due either to portal tumour thrombus or at the site of intrahepatic metastasis, 36 underwent debulking resection only because of limited liver function, and four had extrahepatic disease. The case records of the remaining 386 patients were reviewed. After operation patients were followed every 3 months by measurement of serum α-fetoprotein (AFP) levels, ultrasonography, computed tomography and, if necessary, hepatic angiography. Recurrence was defined clinically as new lesions with features of HCC by more than two imaging methods[9]. The distribution of intrahepatic recurrence in relation to the main tumour at the primary resection was classified on the basis of segmental liver anatomy as follows: (1) segmental, when the tumour recurred in the same Healey segment[10]; (2) ipsilobar, in the segment adjacent to the resected primary lesion in the ipsilateral lobe; (3) contralobar, in the lobe contralateral to the resected primary lesion; (4) bilobar, in both lobes; and (5) diffuse, diffusely as numerous foci throughout the whole remnant liver. The follow-up period ranged from 2·1 to 111·3 (median 38·8) months. Patients without recurrence were followed for at least 6 months after surgery.

The following factors were analysed with reference to their prognostic significance in recurrence: age, sex, status of hepatitis virus infection, associated liver cirrhosis, hepatic reserve according to the Child classification, serum AFP level, operative blood loss, perioperative blood transfusion (either during surgery or within 1 week afterwards), surgical procedure, the number and size of the tumour(s), presence of portal venous invasion and/or intrahepatic metastasis, presence of a fibrous tumour capsule, width of the tumour-free margin, and Edmondson–Steiner's histological grading The surgical procedure was defined according to the segmental anatomy of the liver: lobectomy, resection of a hemihepatic lobe; segmentectomy, resection of a segment according to Healey's definition; subsegmentectomy[11], resection of Couinaud's segment[12]; limited resection, all other forms of non-anatomical resection less extensive than segmentectomy. Recurrence rates were calculated by the Kaplan–Meier method and differences between recurrence curves were assessed with the log rank test. The Cox proportional hazards model was used to determine the variables most significantly related to disease recurrence[13].

Results

Clinicopathological data at primary resection

Men outnumbered women by 311 to 75, and the mean age was 59·7 (range 19–80) years. Some 362 patients (93·8 per cent) had histologically proven chronic liver disease, including 229 (59·3 per cent) with cirrhosis and 133 (34·5 per cent) with chronic hepatitis. The serum level of AFP ranged from 2·5 to 749 626 (mean 450) ng/ml. Some 294 patients (76·2 per cent) had a solitary tumour. The mean maximum diameter of the tumours was 4·2 (range 0·9–26) cm. Microscopic portal venous invasion and/or intrahepatic metastases were found in 186 patients (48·2 per cent) and the tumour had a fibrous capsule in 327 (84·7 per cent). The surgical procedure was limited hepatic resection in 223 patients (57·8 per cent), subsegmentectomy in 70 (18·1 per cent), segmentectomy

Paper accepted 14 December 1995

in 46 (11·9 per cent) and lobectomy in 47 (12·2 per cent). Mean operative blood loss was 1015 (range 40–7500) ml and 85 patients (22·0 per cent) received blood transfusion during the operative period.

Patients with recurrence

Among the 386 patients, 219 (56·7 per cent) developed recurrence during the follow-up period of 1·5–84·2 (median 38·2) months. Of these 219 patients, tumour recurrence was confined to the remnant liver in 189 (86·3 per cent). Both intrahepatic and extrahepatic recurrence of the tumour was recognized in 19 patients. In 11 patients only extrahepatic organs were involved: lung (four patients), bone (three), lung and brain (one), lung and peritoneum (one), bone and lymph node (one), and bone and pharynx (one).

Time to recurrence

Among the 189 patients who developed recurrence in the liver only, 128 (67·7 per cent) did so during the first 2 years after surgery. Nine of 10 patients with a normal liver had intrahepatic recurrence within 2 years after resection, whereas in those with cirrhosis 47 (35·3 per cent) of 133 developed recurrence confined to the liver after 2 years (*Fig. 1*). The median (range) time to recurrence in relation to the state of the non-cancerous liver parenchyma was 7·9 (1·8–84·2) months in patients with a normal liver, 13·4 (2·0–79·5) months in those with chronic hepatitis, and 16·7 (1·5–73·1) months in those with cirrhosis.

*The significance of the difference for each parameter was tested by the log rank test modified for censoring; n.s., not significant segment. Other ipsilobar recurrence was also seen in a further one-quarter of the patients. Considering only the 129 patients with a solitary tumour who underwent resection less extensive than segmentectomy, the tumour recurred three times more frequently in the ipsilateral than in the contralateral lobe (*Table 1*).

Analysis of factors predictive for recurrence

When the cumulative recurrence rate was compared among the various subgroups identified by each predictive factor, associated liver cirrhosis, poor hepatic reserve (Child grade B or C), multiple tumours, presence of portal venous invasion and/or intrahepatic metastasis, and perioperative blood transfusion were found to be significantly related to a shorter time to recurrence (*Table 2*). However, the prognostic variables shown to be significant by multivariate analysis were portal venous invasion and/or intrahepatic metastasis, liver cirrhosis and blood transfusion (*Table 3*).

Table 3 Significant prognostic factors for recurrence of 386 resected hepatomas

Performed (1)	85	1·47 (1·10–1·97)	0·01

*Forward and backward stepwise analyses were used to select these variables. †Relative risks were expressed as the exponential coefficients and reflected increased hazards of the 0-coded factor; values in parentheses are 95 per cent confidence intervals. ‡Cox proportional survival analysis

Survival after recurrence

Of the 219 patients who developed recurrence, 127 (58·0 per cent) died, with a median survival time of 51·7 months. The median survival time after the diagnosis of recurrence was 30·8 months.

Discussion

Despite the improved safety of surgical therapy, recurrence of HCC after surgery remains common. In this study most of the patients who died had recurrence, so the prevention of recurrence is important if overall survival is to improve.

Portal venous invasion and/or intrahepatic metastasis is one of the most important predictive variables for recurrence, as has been reported previously[14,15]. The fact that more than half of all of the observed intrahepatic recurrences were either in the same Healey segment or in the segment contiguous to the primary resected site in the ipsilateral lobe suggests intrahepatic spread of hepatoma in a segment-by-segment manner via the portal venous system[8,11]. Although two reports[2,6] have described a similar pattern of intrahepatic recurrence, they included only a limited number of patients, and in one report local recurrence was defined as including recurrent tumour in the contralateral lobe after hepatic lobectomy[2]. Other surgeons have reported various rates of local recurrence (14–21 per cent)[3,5,7], but they did not define the distribution of recurrence strictly with regard to the anatomy of hepatic segments.

Some authors advocate a wide surgical margin to improve surgical outcome[16–19]. In the present study the presence of a tumour-free margin (more than 10 mm) did not show the prognostic benefit that other authors have reported[15,20]. Considering the possibility of portal system-based spread, complete removal of the portal area containing the tumour might be more important for curative resection than non-anatomical resection with a wide surgical margin. Although the surgical procedure did not significantly influence the frequency of recurrence, this may have occurred because limited hepatic reserve did not permit a resection wide enough to encompass the full extent of the tumour in many patients with cirrhosis. As the authors have previously reported, anatomical hepatic resection provides a better surgical result, especially when the patient has a non-invasive tumour in a non-cirrhotic liver[1].

Recurrent HCC after resection arises either from non-excised cancer or from *de novo* primary tumours. Unarrested carcinogenesis in the cirrhotic parenchyma is thought to be responsible for the *de novo* appearance of multifocal tumours. However, detectable adenomatous hyperplasia, which has been proven to be a precancerous lesion, requires 2 years or more for transformation into HCC[21]. In fact, in the present study a second peak of recurrence was observed at 2–2·5 years after surgery in cirrhotic patients (*Fig. 1*).

The number of tumour(s) and hepatic reserve, which were identified as being significantly associated with a shorter time until recurrence, had no independent prognostic significance because of the overriding effect of other predictors in multivariate analysis.

These results do not support simple wide resection but rather suggest an anatomically extended resection within safe limits. Late recurrence in the form of a second new tumour arising from multicentric foci would appear to warrant repeat surgery[22,23]. It also seems beneficial, with respect to cancer recurrence, to operate on patients with HCC using an approach that minimizes or avoids the need for blood transfusion[24].

Randomized trial of periportal peritoneal bupivacaine for pain relief after laparoscopic cholecystectomy

D. J. ALEXANDER, S. S. NGOI, L. LEE, J. SO, K. MAK, S. CHAN and P. M. GOH

Department of Surgery, National University Hospital, Singapore
Correspondence to. Mr D. J Alexander, Department of Surgery, York District Hospital, Wigginton Road, York YO3 7HE, UK

The aim of this study was to determine whether injection of a long-acting local anaesthetic, in relation to the port sites at the level of the parietal peritoneum, would reduce postoperative pain following laparoscopic cholecystectomy. Patients were entered into a randomized, prospective, double-blind study comparing the effects of a standard technique, in which bupivacaine (total of 20 ml, 0·5 per cent) was injected into the subcutaneous periportal tissue around the four port sites, and a technique in which bupivacaine (total of 20 ml, 0·25 per cent) was injected into the subcutaneous periportal tissue as above with the addition of periportal parietal peritoneal injection of bupivacaine (total of 20 ml, 0·25 per cent). Two scores for pain, with the patient at rest, and on movement, were assessed 6 and 18 h after surgery using a visual analogue pain scale. Median pain score was significantly higher in patients who received standard technique ($n = 40$) than in those given peritoneal injection ($n = 40$) at both 6 (rest = 3·0 *versus* 1·0, movement = 5·0 *versus* 2·9) and 18 h (rest = 1·9 *versus* 0, movement = 3·2 *versus* 1·2). Both opiate and oral analgesic requirements were reduced in patients administered peritoneal injection, although this was not statistically significant. The addition of periportal injection of bupivacaine at the level of the parietal peritoneum, performed under direct vision, reduces pain after laparoscopic cholecystectomy.

Day-case cholecystectomy is established[1], because of the reduction in postoperative pain associated with the laparoscopic approach[2]. There is still a significant degree of abdominal discomfort in the immediate postoperative period[3,4]. Postoperative pain is localized to the epigastrium and right upper quadrant, in direct relation to the port sites and the area between them. This pain is not abolished by periportal subcutaneous injection of long-acting local anaesthetic. Trauma to the parietal peritoneum at the port sites may be responsible for postoperative pain. The purpose of this study was to determine whether an additional injection of long-acting local anaesthetic around the port sites, at the level of the parietal peritoneum, would reduce postoperative pain.

Patients and methods

The study comprised a consecutive series of patients who had laparoscopic cholecystectomy by one of three participating consultants at the National University Hospital, Singapore. A standard four-port technique was used with two 11-mm ports placed in the supraumbilical region and epigastrium, and two 5-mm ports in the subcostal area at the mid-clavicular and anterior axillary lines. At the time of induction of general anaesthesia the patients were randomized, using sealed envelopes, to either: (1) standard therapy, in which, after cholecystectomy, a total of 20 ml bupivacaine (0·5 per cent) (Astra Pharmaceuticals, Kings Langley, UK) was injected into the subcutaneous tissue around the four port sites; or (2) peritoneal injection, in which a total of 20 ml bupivacaine (0·25 per cent) was injected around the port entry sites, at the level of the parietal peritoneum, under direct vision using a 23-cm laparoscopic obstetrics and gynaecology needle, of internal diameter 1·5 mm (used for draining ovarian cysts). The injection was considered satisfactory once a bleb had been raised around the port entry site, usually as a result of peritoneal puncture both behind and in front of the trocar. The midline epigastric port and medial right hypochondrial port sites were injected by introducing the needle through the lateral right hypochondrial port. This latter site was injected by introducing the needle through the midline epigastric port. The camera was then removed from the umbilical port which was visualized internally with the camera through the epigastric port. The umbilical port site was injected by introducing the needle through the lateral right hypochondrial port. These patients (peritoneal injection) also received a total of 20 ml bupivacaine (0·25 per cent) in the subcutaneous tissue around the four port sites.

All patients were prescribed postoperative analgesia of oral naproxen sodium (Synflex, (Roche Products, Welwyn Garden City, UK) two 550 mg tablets) and/or intramuscular pethidine (50 mg) as required. Intraoperative opiate analgesia was given at the discretion of the anaesthetist irrespective of the study group, and was recorded prospectively.

Patients were studied at 6 and 18 h after surgery using a visual analogue pain scale (VAPS). A 20-cm grid, without numeration, was constructed and the patient asked to mark a point related to his or her current pain level having been advised that the bottom represented 'no pain' and the top 'worst imaginable pain'. In an effort to standardize this subjective assessment, it was suggested to the patient that a level at the mid-point or greater meant that they were unable to walk unaided. Patients were asked to mark the pain chart at two points at each time of study, referring to level of pain at rest and on movement. The scores were obtained by a 'blinded' independent observer. The patients were unaware of their randomization and this information was kept separate from the notes and operative report. Similarly, the ward nurses were unaware of the randomization and gave out analgesia in the normal way. In most cases the patients were lucid enough to cooperate in the study; however, if there was doubt a simple test was constructed in which the patient was asked to count the number of 'P's in a given sentence. If the patient could not comply, or was asleep, the research assistant returned an hour or two later (thus giving a narrow range to the precise times studied).

Information related to American Society of Anesthesiologists (ASA) grade, operative details, intraoperative and postoperative analgesic consumption, and outcome was collected prospectively.

Comparisons between groups were tested by the Mann–Whitney *U* test, where $P < 0·05$ was considered significant.

Results

Eighty-three consecutive patients were entered into the study. Three were excluded because of conversion to an

Table 3 Analgesic requirement during and after laparoscopic cholecystectomy

	Patients given standard therapy	Patients given peritoneal injection
Intraoperative morphine (mg)	6	6
Postoperative pethidine (mg) per patient (i.m.)	36	23
Postoperative naproxen (mg) per patient (o)	116	127

Values are medians. Differences are not significant. Analgesia was supplied in 50-mg increments of intramuscular pethidine and 550-mg (×2) increments of naproxen sodium. i.m., Intramuscular; o, oral

open procedure after randomization (this was the result of difficulties in delineating the anatomy due to chronic cholecystitis in each patient). Patient details and indications for surgery were similar in each group (*Table 1*). The ASA grade was 1 in 68 per cent of patients who received standard technique *versus* 83 per cent in those who were given peritoneal injection. The remainder were grade 2. There were no major complications; minor intraoperative complications included peritoneal bile contamination (five standard technique *versus* three peritoneal injection), peritoneal blood contamination (none standard technique *versus* two peritoneal injection), peritoneal bile and blood contamination (three standard technique *versus* two peritoneal injection) and one gallbladder perforation in each group. The use of a 5-mm suction drain to the gallbladder bed was confined to ten patients given standard technique and eight who received peritoneal injection.

There was a significant reduction in the median VAPS in the study group at both 6 and 18 h after operation, both at rest and on movement (*Table 2*) in patients who had peritoneal bupivacaine. The median intraoperative analgesia given was identical in each group at 6 mg morphine (*Table 3*). Median postoperative intramuscular opiate and oral analgesic requirements were also similar in both groups.

Discussion

This study has confirmed a clinical impression that direct periportal injection of bupivacaine, at the level of the parietal peritoneum, reduces postoperative pain. This technique adds 2–3 min to the overall procedure and is easy to learn. It is performed under direct vision and is therefore safe. The benefits of good control of immediate postoperative pain, allowing swift mobilization, continue well past the time that the effect of the local anaesthetic is likely to have worn off[5]. The significant discomfort found in the control group is similar to that noted in a previous study from the authors' department when only pain scores at rest were obtained[3]. Other studies have reported significant pain in the first 48 h after laparoscopic cholecystectomy[4,6].

The use of intraperitoneal local anaesthetic at laparoscopy is not new, although to the authors' knowledge direct infiltration into the peritoneum around the port entry sites has not been performed before. Diagnostic laparoscopy is a common outpatient procedure, particularly for gynaecological complaints, and shoulder-tip pain is reported in as many as 35–63 per cent of cases afterwards[7]. The aetiology of shoulder-tip pain is presumed to be a residual pocket of subdiaphragmatic gas above the right lobe of liver. Using a visual analogue scale, Narchi *et al.*[8] found intraperitoneal infiltration of local anaesthetic into the right subdiaphragmatic area to reduce postoperative scapular pain after diagnostic laparoscopy.

Rademaker and colleagues[9] investigated the potential analgesic effect of bupivacaine instillation into the right subdiaphragmatic area in patients undergoing laparoscopic cholecystectomy. Although no benefit was reported, the precise localization of the pain was not specified and it is the authors' experience that patients undergoing laparoscopic cholecystectomy rarely suffer from postoperative shoulder-tip pain, although up to 80 per cent of patients may be affected in the first 24 h after gynaecological laparoscopy[10]. In one study, 55 per cent of patients also complained of abdominal pain some 48 h after gynaecological laparoscopy[10]. The difference in incidence of shoulder-tip pain may be positional. Laparoscopic cholecystectomy is generally performed in a slight reverse Trendelenburg position, the opposite of laparoscopic pelvic surgery. During laparoscopic cholecystectomy any spilled blood or bile collects in the paracolic gutter and supracolic compartment. It is routine to suction this area precisely, thus also evacuating any gas pocket.

Narchi *et al.*[11] performed peritoneal biopsy 2–3 days after laparoscopy and demonstrated peritoneal inflammation resulting from capillaries torn at the time of abdominal distension. Gillberg and colleagues[12] investigated 46 women who had gynaecological laparoscopy and found postoperative pain to be significantly reduced when a non-steroidal anti-inflammatory drug was given before anaesthesia. Pain resulting from stretching the whole parietal peritoneum should be less specific and more generalized than that found in previous studies. The total dose of bupivacaine was limited to 20 ml of 0·5 per cent for each patient, less than that used safely by Narchi *et al.*[8], to avoid potential toxicity. In addition, by raising an intraperitoneal bleb, the effect is likely to be a slower release into the circulation than in the case of direct instillation. Bupivacaine was diluted with 20 ml sterile water in the treatment group, to give the same total volume of anaesthetic subcutaneously to patients in both groups, although this meant that patients in the study group (peritoneal injection) had a reduced concentration of subcutaneous local anaesthetic injected.

This technique of periportal bupivacaine injection is simple, quick and reduces immediate postoperative pain after laparoscopic cholecystectomy.

Cost–utility analysis of home parenteral nutrition

D. M. RICHARDS and M. H. IRVING

University of Manchester Intestinal Failure Unit, Hope Hospital, Salford M6 8HD, UK
Correspondence to: Mr D. M. Richards

An economic evaluation of home parenteral nutrition (HPN) for intestinal failure is presented. The cost–utility of HPN and factors affecting the cost–utility ratio were examined to determine whether current practice is the most efficient way of treating intestinal failure. Quality-adjusted life-years (QALYs) gained were measured using a validated health status questionnaire. The cost of treating a patient with intestinal failure was calculated, and marginal cost per QALY gained ratios were obtained. The cost per QALY for an average patient was approximately £68 975, but the value for patients over 55 years of age of about £126 865 compared with approximately £58 233 for those under 44 years. Treating a patient in hospital rather than at home increased the estimated cost per QALY to approximately £190 000. The current practice of home care is about 65 per cent more cost-effective than hospital care.

Home parenteral nutrition (HPN) is a life-saving but expensive treatment for intestinal failure. Intestinal failure is defined as the failure of intestinal function to provide sufficient nutrients and fluids to meet metabolic requirements. Patients with intestinal failure would be subjected to a combination of dehydration and malnutrition without HPN, and there would be an almost inevitable progression to death[1].

The treatment involves the administration of nutrient solutions through a long-term central venous catheter. HPN is complex and time-consuming for the patient and involves an average of 2–3 weeks of training[2].

In the face of budget constraints and increasing demands on healthcare, it is important that all healthcare interventions demonstrate cost-effectiveness when compared with alternative treatments and other healthcare programmes. This need is reflected in the current National Health Service (NHS) Research and Development Strategy and in particular the Health Technology Assessment Programme, in which evidence of effectiveness, quality-of-life assessment and economic appraisal has a high priority. In addition, following the purchaser–provider split within the NHS, cost-effectiveness data will play an integral part in contract setting.

As with similar technologies, HPN programmes are competing for increasingly scarce resources, and there is an urgent need for this type of assessment. To date, the authors are not aware of any economic appraisal of HPN from the UK.

Cost–utility analysis is an economic tool for assessing healthcare programmes and is useful for comparing different treatments for the same condition (assessing operational efficiency) or different technologies across the healthcare spectrum (assessing allocative efficiency). It evaluates outcomes in terms of utility, which is used as a measure of satisfaction. The most common method of representing utility is the quality-adjusted life-year (QALY). QALYs are the units of measurement resulting from the product of data on survival and quality of life[3], and are the measurement of outcome used in a cost–utility analysis. It is important to calculate the resources consumed by a technology and convert these into a monetary equivalent. The marginal cost, the cost to treat one additional patient, is the most useful measure of resource consumption. The costs are combined with the outcome (QALYs gained) to give a ratio of cost–utility. Different technologies can then be compared on a marginal cost per QALY gained basis.

Cost–utility analysis has been used in this setting for two main reasons. First, it gives an indication of the quality of the life-years gained, an important factor for patients receiving HPN. Second, the main concern is with allocative efficiency, determining whether HPN treatment is worthwhile compared with other healthcare programmes. If other treatments were available for intestinal failure then they could be compared on a cost–utility basis, but as there are no viable alternatives at present HPN has been compared with the alternative of no treatment.

Patients and methods

Objectives

The study was designed to measure the cost–utility of HPN, to examine factors affecting the cost–utility ratio and to determine whether current practice is the most cost-effective way of treating patients with intestinal failure.

The alternatives

Patients are trained in hospital for approximately 3 weeks and then discharged. They look after the central-line and carry out the complex procedure of fluid administration. Admissions to hospital are restricted to times when complications arise; these are usually central-line or metabolic derangements. There are no viable alternatives that can be considered at the present time, apart from keeping patients with intestinal failure in hospital or admitting them for intermittent therapy. This policy has been shown to be less cost-effective[4], and almost impossible for the present cohort of patients, as they lived an average of 85 miles from the unit and fed for a median of 6 nights per week. Small bowel transplantation is a developing future option[5], but owing to problems with immunosuppression it is not widely available[6]. HPN would still be required while donor organs were awaited.

Perspective

This study has been performed from the broad perspective of the NHS. It includes costs relevant to the NHS but does not explore the cost to individual patients, such as change in employment status, travel costs and time.

Paper accepted 23 November 1995

Patients

There are three main centres providing HPN services in the UK: Hope Hospital in Salford, St Mark's Hospital in London and Dundee Royal Infirmary. However, because there are a further 47 centres with only a handful of patients each, there will be inevitable variation in practice throughout the country. The results from different centres will vary according to the experience of the centre[7]. The resources used will be subject to variation due to local factors affecting costs; in particular, the cost of the parenteral solutions will vary according to the supplier It was decided, on the basis of variation in practice and costs, that the authors should concentrate on patients curently monitored by Hope Hospital. The explicit presentation of the results meant that local factors could be taken into account, and 'centre-specific' QALY values calculated.

Hope Hospital monitors the largest group of patients receiving HPN in the UK ($n = 64$, June 1995), equivalent to approximately 35 per cent of the total UK population of patients having HPN[8]. There is extensive information on survival and morbidity rates[2]. The patients were treated according to standard protocols and monitored by a multidisciplinary nutrition team. The mean age was 44·4 (range 17–70) years, and 40 were women. All patients were suffering from intestinal failure, the commonest diagnosis being Crohn's disease ($n = 35$, 55 per cent) followed by mesenteric vessel occlusion ($n = 11$, 17 per cent) and volvulus ($n = 8$, 12 per cent). The remaining ten patients had a variety of diagnoses. None of the patients had acquired immune deficiency syndrome (AIDS) or active cancer. All had received at least 6 months of nutrition at home. The median duration of HPN treatment was 4 (range 0·5–15) years, HPN being infused on a cyclical nocturnal basis in 63 patients for a median of 6 (range 2–7) nights per week.

Methodology

The utility scores were obtained using the EuroQol Health Status Questionnaire[9]. This validated subjective instrument yields an index on a scale of 0 to 1. A score of 1 would be the best possible quality of life, while 0 would be equivalent to death. A range of survival times was considered because of uncertainty regarding survival outcomes. This methodology was used by Gudex[10] when dealing with the same problem.

The number of QALYs gained was calculated by multiplying length of survival by the quality-of-life index. They were discounted at the rate published by the UK Treasury (6 per cent per annum). Non-discounted values are also presented, reflecting the view that there is no time preference for health outcomes. The QALYs gained are calculated assuming that life is not possible for patients with intestinal failure without HPN[1].

The marginal costs (the cost to treat one additional case of intestinal failure) were calculated assuming that there was some spare capacity in the unit and that no additional buildings or staff were required. The determination of marginal costs was carried out in three phases, according to the methodology described by Drummond[11]: (1) enumeration of the resources used, i.e. a list of all the resources thought to be relevant (*Appendix 1*); (2) measurement of resource use, i.e. the actual number of resources consumed; and (3) the explicit valuation of resources, valuing the resource consumption in terms of money (future costs discounted at 6 per cent).

Cost–utility ratios were calculated for a range of survival times. A sensitivity analysis was performed to examine the factors affecting the cost–utility ratios. The factors explored were age, hospital admission and length of survival without HPN.

Results

The mean utility score derived from the EuroQol instrument for patients with HPN was 0·52. The score was 0·61 for patients under 44 years and 0·28 for older patients.

The costs for the first year are given in *Table 1*. Subsequent years will not include the cost of a pump, trolley, drip stand, fridge and hospital training; therefore the costs for the second year onwards (non-discounted) were £36 848. The incremental discounted costs for each year of survival are shown in *Table 2*. The total discounted cost for (median) 4 years of treatment is £142 089. If a patient is treated as an inpatient for the 4 years then the discounted cost increases to £312 595. The potential savings for home rather than hospital HPN for the median duration of 4 years are £170 506.

The number of QALYs gained for each year of survival is shown in *Table 2*. It will be some years before the survival of the present group of patients is known, and cost–utility ratios are therefore presented for a range of survival times in *Table 2*. The marginal cost per QALY gained for a patient surviving for 4 years is £68 975. If longer survival is experienced, then the marginal cost per QALY falls.

Sensitivity analysis

The utility score for a patient who manages to survive without HPN has been estimated at 0·18[4]. This figure would mean that the QALY gain would be reduced to only 0·34 for a patient with HPN surviving 1 year, and the cost per QALY would then increase from £85 829 to £130 259. If the discount rate is reduced to 0 per cent, the cost per QALY for a patient surviving 4 years would be

Table 1 Costs to the National Health Service for year 1

	Cost (£)
In-hospital stay for training and line insertion (including all staff, hotel and investigation charges for 3 weeks)	4513
In-hospital TPN and disposable charges	1428
Outpatient monitoring (four visits)	600
Pump, trolley, fridge and drip stand	3590
Home TPN for 6 nights per week (median) (using a home-care company supplying disposables for 49 weeks)	34157
Total	44288

TPN, total parenteral nutrition

Table 2 Quality-adjusted life-years gained, incremental costs and marginal costs per quality-adjusted life-year gained for a range of survival times

Years survived	QALYs gained	Discounted incremental cost (£)	Marginal costs per QALY gained (£)
1	0·516	44288	85829
2	1·03 (0·97)	78925	76626
3	1·55 (1·29)	111484	71925
4	2·06 (1·61)	142089	68975
5	2·58 (1·89)	170857	66224
6	3·10 (2·14)	196277	63315
7	3·60 (2·34)	220172	61159
8	4·12 (2·52)	242633	58891
9	4·64 (2·66)	263747	56842
10	5·16 (2·78)	283594	54734

Values in parentheses are the number of quality-adjusted life-years (QALYs) gained discounted at 6 per cent

£75 161. At a 10 per cent discount rate this value would fall to £65 126. The present patients were not kept in hospital for long-term HPN but the effect can be estimated. The utility fell by 20 per cent when Torrance *et al.*[12] measured the difference between home and hospital renal dialysis. If the same fall is assumed when patients with HPN are kept in hospital, then a patient treated in hospital for the median 4 years would gain only 1·65 QALYs. The discounted hospital costs for this period are £312 595 and the cost per QALY is therefore £189 451.

Younger patients had higher utility scores (0·61), and this reduces the cost per QALY to £58 233. For older patients the cost per QALY rises to £126 865 because of the lower utility (0·28). One of the commonest complications of HPN is central-line sepsis. Two episodes of line sepsis (in years 2 and 4), which required attempted salvage and replacement of the central line, led to a discounted direct cost of £3660. This sum increases the cost per QALY over 4 years to £70 751.

Discussion

Economic appraisals of HPN have rarely been performed, particularly in the UK. This fact is surprising considering the costs associated with HPN programmes. Wateska *et al.*[13] analysed costs of HPN compared with those of hospital total parenteral nutrition (TPN) and noted a cost reduction of 73 per cent for HPN. Other cost analyses have also demonstrated that HPN is 72–81 per cent cheaper than hospital treatment[14 15]. Baptista and co-workers[16] suggested regular reassessment for compliance, appropriateness of formulation, infusion regimen, bowel adaptation and oral intake so that optimum cost-effective care can be provided for an individual.

Detsky *et al.*[4] performed a cost–utility analysis of HPN in Toronto, which was based on utility scores measured in 37 patients and estimated for a further 36. Detsky[17] has admitted that the scores they obtained were higher than those expected (0·7 on a scale of 0 to 1). This study measured the net savings in healthcare costs as $19 232 (1986 Canadian) per patient. The cost per QALY was estimated to be $27 375 (1986 Canadian).

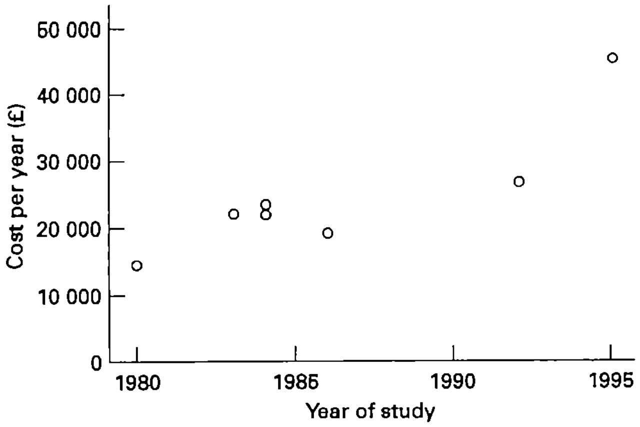

Fig. 1 Annual cost of home parenteral nutrition cited by different authors (from left to right, References 13–16, 4, 18 and the present paper respectively)

Unfortunately, there are few alternatives to HPN. At present the only possible alternative to home treatment is keeping the patient in hospital, or admission for intermittent therapy. Small bowel transplantation is not yet considered a routine procedure, although there are hopes that one day it may replace the need for long-term HPN[6]. Patients waiting for a small bowel transplant would still need HPN during the period of observation necessary to assess the degree of adaptation.

This study has confirmed that HPN is an expensive technology. The costs are escalating in excess of inflation (*Fig. 1*). However, HPN is life-saving for many patients. The quality-adjusted survival for younger patients (under 44 years) is significantly better than that for older (over 55 years) patients, and this fact significantly reduces the marginal cost per QALY. The longer a patient survives on HPN the more cost-effective the treatment becomes. Weaning from HPN due to intestinal adaptation reduces the cost per QALY even further.

Detsky *et al.*[4] estimated the increase in quality-adjusted survival as 3·3 years, compared with the alternative of treating the patient in hospital. Messing and co-workers[19] measured the survival of a cohort of 217 patients. No patients were lost to follow-up, and the probability of survival for benign conditions at 5 years was 62 per cent. In the USA and Italy malignant disease is the commonest indication for HPN, and AIDS is an increasing indication. There were no patients with AIDS or terminal malignant disease in the present study, but if they were included the survival rate would drop sharply and consequently the cost per QALY would rise steeply.

This study has shown that HPN is more cost-effective than hospital care. The estimated savings for each patient (on TPN for 4 years) treated at home rather than in hospital are £170 506. The cost per QALY for hospital care was almost £190 000 and £68 975 for HPN. This figure means that the cost–effectiveness of home care is approximately 65 per cent greater.

The sensitivity analysis showed that the cost per QALY was sensitive to the possibility of survival without HPN. HPN is therefore most cost-effective when it is used as a life-saving technology. Although it is difficult to see how a patient could be kept as an inpatient for the duration of required therapy, this alternative had to be considered and the cost per QALY was found to be very high. Because of the fall in utility values associated with patients over the age of 55 years, the results were sensitive to age. Altering the discount rate or treating line sepsis during the course of HPN treatment did not significantly affect the results. It should be remembered that QALYs are not without their critics[20,21], but measuring and valuing the quality of life is an extremely difficult process.

League tables showing 'marginal cost per QALY gained' have been constructed to compare different healthcare interventions. When HPN treatment is compared with home haemodialysis, it appears that HPN is much less cost-effective (£69 000 per QALY compared with £23 500). However, intestinal function recovers in approximately 75 per cent of patients with Crohn's disease, and HPN becomes much more competitive on a cost-per-QALY basis because of the consequent increase in QALYs gained. There have been criticisms of cost-per-QALY tables because of the differing methodologies used and failure to use marginal costs[22]. Despite the criticisms, explicit presentation of cost-effectiveness is an improvement on the implicit decision-making process of the past. In Oregon, USA, different treatments have been competing for scarce resources with regard to the marginal cost per QALY gained[23].

In conclusion, HPN is an expensive technology with a reasonable outcome for younger patients with benign disease in terms of the number of QALYs gained. The cost-effectiveness of HPN is lower for older patients and those in hospital care. HPN is approximately 65 per cent more cost-effective than keeping patients in hospital. The expense of the treatment is offset by the life-saving nature of the technology.

Randomized controlled trial of the effect of mannitol on renal reperfusion injury during aortic aneurysm surgery

M. L. NICHOLSON, D. M. BAKER, B. R. HOPKINSON and P. W. WENHAM

University Hospital, Nottingham, UK

Correspondence to: Mr M. L. Nicholson, Department of Surgery, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK

The effects of mannitol on renal impairment following infrarenal aortic aneurysm repair were studied. Patients received either mannitol 0·3 g/kg ($n = 15$) or saline ($n = 13$) as a rapid intravenous infusion before aortic cross-clamping. One patient in the control group developed fatal postoperative renal failure but there was no renal failure in the mannitol group. Two patients treated with mannitol died from perioperative myocardial infarction. There were no significant differences in postoperative blood urea level, serum creatinine concentration or creatinine clearance between mannitol and control groups. In patients who had mannitol there was a significant diuresis on the first day after operation (mean urine output 2250 ml) compared with before operation (1557 ml) ($P = 0·007$). Compared with controls, patients treated with mannitol had lower mean(s.e.m.) postoperative levels of urinary albumin (160(32) *versus* 500(140) mg per mmol creatinine; $P = 0·036$) and *N*-acetyl glucosaminidase (143(34) *versus* 271(70) μmol per mmol creatinine; $P = 0·04$) indicating a reduced level of subclinical glomerular and renal tubular damage. These data demonstrate that mannitol reduces subclinical renal injury following infrarenal aortic aneurysm repair.

Acute renal failure is a serious complication of both emergency and elective aortic aneurysm repair, and is associated with a high mortality rate[1]. The cause of postoperative renal dysfunction is likely to be multifactorial, but aortic cross-clamping, which is necessary during this surgery, is an important factor. Such clamping is associated with marked changes in renal haemodynamics and subsequent reperfusion injury, both of which adversely affect renal function[2,3]. The protective effect of mannitol in preventing ischaemic renal damage has been studied previously[4–6] and some surgeons use it routinely during aortic aneurysm surgery. In this study a controlled trial was designed to test the effects of mannitol on renal function and injury following aortic aneurysm repair.

Patients and methods

Twenty-eight consecutive patients undergoing elective aortic aneurysm repair were entered into a prospective randomized trial. All operations were performed under general anaesthesia with the patients paralysed and mechanically ventilated. An epidural catheter was placed before operation, unless contraindicated, and the anaesthetic agents used were fentanyl, etomidate, isoflurane and nitrous oxide in oxygen. A urinary catheter was placed in all patients after the induction of anaesthesia. Patients were then randomly allocated to receive either mannitol 0·3 g/kg or an equivalent volume of normal saline given as a rapid intravenous infusion before cross-clamping the aorta. Randomization was by means of opening a sealed envelope following the induction of anaesthesia. The sealed envelopes were generated using a table of random numbers. All operations were performed by, or under the direct supervision of, two consultant surgeons (P.W.W. and B.R.H.). After administration of systemic heparin 3000–5000 units, the infrarenal aorta and iliac arteries were clamped. The aneurysm sac was then opened and replaced with either a straight or bifurcated Dacron graft (Du Pont, Stevenage, UK), depending on the distribution of the aneurysmal disease.

Assessment of renal function and injury

Renal function was assessed after operation by measuring urine output, creatinine clearance, and blood urea and serum creatinine levels. Renal failure was defined as urine output below 400 ml per 24 h and/or the need for dialysis. Venous blood was drawn for urea and electrolyte estimation before operation and then at 6 h, 24 h, 3 days and 7 days after surgery. Glomerular filtration rate was estimated by performing 24-h creatinine clearances before operation and then on the first, third and seventh days after operation. Aliquots of urine (10 ml) were collected at the following times: before surgery, after induction of anaesthesia but before mannitol or saline infusion and cross-clamping, 60 min after cross-clamp release, and 6 h, 24 h and 7 days after surgery. These aliquots were stored at −70°C for subsequent batch analysis of urinary albumin, *N*-acetyl glucosaminidase (NAG) and creatinine. Results were expressed as albumin : creatinine and NAG : creatinine ratio.

Statistical analysis

Data are presented as mean(s.e.m.) or 95 per cent confidence interval (c.i.). Discrete variables were compared using Fisher's exact test. Continuous variables were compared using the Mann–Whitney *U* test (for differences between mannitol and control groups), and the Wilcoxon signed rank test (for changes within groups). Statistical significance was accepted at $P < 0·05$.

Results

Patients in the mannitol and control groups were well matched for age, sex and preoperative risk factors (*Table 1*). Operative details are shown in *Table 2*. Aortic cross-clamp time ranged from 29 to 110 (mean 57) min in the mannitol group and from 27 to 102 (mean 53) min in the control group ($P = 0·76$). There were no significant differences between groups for total anaesthetic time and the duration of intraoperative hypotension below 80 mmHg systolic pressure (*Table 2*).

Clinical outcome

Mean(s.e.m.) postoperative stay in the intensive therapy unit was 2·1(0·4) days in the mannitol group and 1·5(0·2)

Paper accepted 14 December 1995

Table 1 Patient characteristics

	Mannitol ($n = 15$)	Control ($n = 13$)
Mean age (years)	68 (65–72)	71 (68–75)
Sex (M:F)	13:2	11:2
Ischaemic heart disease	6	4
Smokers	13	11
Hypertension	5	6
Chronic obstructive airway disease	1	2
Thromboembolic disease	0	1
Diabetes	0	1

Values in parentheses are 95 per cent confidence intervals. There was no significant difference between groups

Table 2 Operative data

	Mannitol ($n = 15$)	Control ($n = 13$)
Graft type		
Straight	11	9
Bifurcated	4	4
Total anaesthetic time (min)	162 (147–177)	175 (159–191)
Duration of intraoperative hypotension (< 80 mmHg) (min)	21 (8–34)	27 (17–37)
Aortic cross-clamp time (min)	57 (43–71)	53 (39–68)
Peroperative blood transfusion (units)	2·6 (1·5–3·7)	2·7 (1·2–4·2)

Values are mean (95 per cent confidence intervals). There was no significant difference between groups

Table 3 Postoperative complications and deaths

Complication	Mannitol	Control
Death	2	1
Renal failure	0	1
Myocardial infarction	2	0
Respiratory failure	1	1
Left ventricular failure	1	0
Atrial fibrillation	1	0
Chest infection	1	2
Trash foot	1	2
Wound dehiscence	0	1
Diarrhoea	2	0

There was no significant difference between groups (Fisher's exact test)

days in the control group ($P = 0·43$). Mean(s.e.m.) total inpatient stay was 10·6(0·4) days in patients who had mannitol and 10·3(0·6) days in controls ($P = 0·62$). Postoperative complications and deaths are shown in *Table 3*. Ten of 15 patients in the mannitol group and six of 13 in the control group suffered one or more postoperative complications. Both deaths in the mannitol group resulted from perioperative myocardial infarction in patients with known ischaemic heart disease and hypertension. There was no postoperative renal failure in the mannitol group. In the control group the single death was a result of multiple organ failure including adult respiratory distress syndrome, acute renal failure and bilateral trash foot. There were no statistical differences between the rates of other major postoperative complications between the two groups (*Table 3*).

Renal function

Changes in levels of blood urea, serum creatinine and creatinine clearance are shown in *Table 4*. There were no significant differences in these three measures of renal function between patients receiving mannitol and controls, and comparing results within each group against time. Perioperative 24-h urine output is shown in *Fig. 1*. In the

mannitol group there was significant diuresis on the first day after surgery compared with before operation. Although urine output over the first day after operation was higher in patients who had mannitol than in controls, the difference was not significant.

Renal injury

Urinary albumin:creatinine and NAG:creatinine ratios are shown in *Figs 2* and *3* respectively. In both mannitol and control groups the ratio of urinary albumin to creatinine increased from the preoperative level to a peak at 24 h after operation and then declined. The albumin:creatinine ratio increased significantly after the induction of anaesthesia but before aortic clamping; it did not decline to the baseline preoperative level by the seventh day after operation. The urinary albumin:creatinine ratio was significantly higher in controls compared with those receiving mannitol at 6 h after reperfusion ($P=0\cdot027$) and at 24 h after reperfusion ($P=0\cdot036$). Urinary NAG:creatinine ratio also increased following anaesthesia and reperfusion, reaching a peak on the third day after operation and then falling by the seventh day. The increase was smaller in the mannitol group than in controls and the NAG:creatinine ratio was significantly higher in control patients than in those given mannitol at 24 h after reperfusion ($P=0\cdot04$). Urinary NAG:creatinine ratio increased after the induction of anaesthesia but before aortic cross-clamping in both mannitol and control groups ($P<0\cdot01$) and had not returned to the baseline preoperative level by the seventh day after surgery ($P<0\cdot01$).

Discussion

Biochemical tests of renal function are relatively insensitive as large changes in function must occur before such biochemical measurements alter significantly. For example, serum creatinine only rises above the upper limit of the reference range when over half the functional mass of renal tissue is lost[7]. It is, therefore, not surprising that there were no significant differences in perioperative renal function between the mannitol and control groups. Similarly, renal failure cannot be used as an endpoint in human studies because the incidence following elective aortic aneurysm is relatively low and a very large number of patients would be needed to demonstrate a difference between therapies. For these reasons, renal injury was also assessed by measurement of urinary albumin and NAG excretion. Albuminuria is known to be an accurate index of renal glomerular damage[8]. Urinary albumin excretion has been shown to rise rapidly during aortic surgery, and appears to be a useful measure of reperfusion injury and a predictor of the development of postoperative pulmonary complications[9]. NAG is one of over 30 enzymes found in the urine. It is predominantly a proximal tubular cell lysozymal enzyme and its excretion provides an early indicator of renal tubular damage[10]. Urinary NAG measurement is a sensitive index of subclinical renal impairment in obstructive jaundice[11]. To take account of differing urinary flow rates and to correct for differences in dilution, the urinary excretion of albumin and NAG were expressed as ratios to urinary creatinine clearance. These two indices provide a sensitive assessment of subclinical renal damage and allow a useful comparison between groups in a situation where there are no apparent clinical differences.

The data show that there is subclinical renal impairment during elective aortic aneurysm repair and that mannitol has a protective effect on this. The only instance of postoperative renal failure developed in a patient in the control group and this proved to be fatal. This study may contain a type II statistical error and it may be possible to demonstrate a clinically significant effect of mannitol if larger numbers of patients are studied. Although it is probable that clinical rather than subclinical renal impairment is more likely to occur in cases of ruptured abdominal aortic aneurysm, this is a much more difficult situation in which to conduct a clinical study.

The mechanism of renal injury following aortic aneurysm repair has been the subject of much debate. In particular, the effects of aortic cross-clamping have been controversial, and the extensive experimental and clinical literature on this subject has been well discussed recently by Welch *et al.*[12]. Infrarenal cross-clamping of the abdominal aorta causes a marked increase in systemic resistance above the clamp, with a 75 per cent increase in renal vascular resistance and a 38 per cent decrease in renal blood flow[2]. In addition, a fall in glomerular filtration rate follows release of the aortic cross-clamp; this can be delayed but not prevented by dopamine[13]. Other mechanisms may also be involved, such as microembolism of the renal vascular bed[14] and stimulation of the renin–angiotensin system[15].

Release of the aortic clamp may be just as important as the changes in renal haemodynamics occurring during cross-clamping. Sudden re-establishment of the circulation to the lower torso and legs causes generation of oxygen-derived free radicals, followed by formation of thromboxane A_2 and activation of neutrophils[16]. Oxygen free radicals and activated neutrophils cause both local and distant tissue damage in a number of organs. For example, reperfusion following aortic aneurysm repair causes pulmonary injury[17]. As a highly oxygenated organ, the kidney is especially vulnerable to attack from the oxygen free radicals of reperfusion[3].

Mannitol has a number of actions which may protect renal function during aortic surgery. Its osmotic diuretic action has been confirmed in the present study in which early postoperative urine output was significantly increased in patients given mannitol. A good urine flow is thought to reduce renal impairment by preventing the precipitation of casts in the renal tubules, but the osmotic effect of mannitol in the renal tubules may also prevent endothelial cell swelling[18]. Mannitol also has beneficial effects on renal haemodynamics and has been shown to increase renal blood flow[19]. Finally, it is a powerful scavenger of the highly injurious hydroxyl radical which is a key mediator in reperfusion injury[3,20]. In this context, mannitol has been shown to attenuate skeletal muscle reperfusion injury in animal models[21] and pulmonary reperfusion injury following infrarenal aortic aneurysm repair in humans[22]. Neither renal haemodynamics nor oxidative stress were directly measured during this study and it is impossible to speculate further on the mechanism of action of mannitol.

In conclusion, this study demonstrates that mannitol has a protective effect against renal injury during infrarenal abdominal aortic aneurysm repair. It is a simple and inexpensive treatment without adverse effects. Further studies are required to evaluate the mechanism of action of mannitol, be it haemodynamic, free radical scavenging, or a combination of both.

Colour-coded duplex assessment alone before carotid endarterectomy

J. GOLLEDGE, R. WRIGHT, N. PUGH and I. F. LANE

Cardiff Vascular Unit, University Hospital of Wales, Cardiff, UK
Correspondence to: Mr J. Golledge, 35 Sullivans Reach, Walton on Thames, Surrey KT12 2QB, UK

This study assessed whether carotid colour-coded duplex imaging can provide sufficient information to investigate patients before carotid endarterectomy. One hundred patients with symptomatic carotid artery disease (amaurosis fugax 24, transient ischaemic attack 38 and established stroke 38) were assessed by both colour-coded duplex imaging and arch angiography. Stenoses were graded at angiography using the linear method from the European Carotid Surgery Trial and on duplex using peak systolic velocity criteria. Angiograms were also analysed for any arch or intracerebral pathology which would alter surgical management. In defining 70–99 per cent stenoses, duplex had a sensitivity of 98 per cent, specificity 96 per cent, positive predictive value 96 per cent, negative predictive value 98 per cent and accuracy 97 per cent compared with angiography for both symptomatic and asymptomatic carotids ($\chi^2 = 1{\cdot}22$, 1 d.f., $P = 0{\cdot}25$). With respect to the symptomatic carotid arteries angiography gave different information from duplex in six patients (6 per cent): definition of 70–99 per cent carotid stenosis was different (four), visualization was poor on duplex (one) and an intracerebral aneurysm was identified by angiography. One patient died following arch angiography as a result of mesenteric thrombosis. Carotid duplex imaging alone would appear to be sufficient to assess most patients before carotid endarterectomy as an accurate, safe and relatively cheap investigation compared with angiography. In cases where duplex assessment does not allow full visualization of the carotid bifurcation angiography is required.

North American[1] and European[2] carotid trials have clearly validated carotid endarterectomy as the optimal treatment for 70–99 per cent internal carotid artery stenoses[3]. Colour-coded duplex imaging technology has improved over the past 5 years, making it possible to visualize the carotid bifurcation and extracranial internal carotid artery without resort to angiography[4]. In a small number of vascular units, patients undergo carotid endarterectomy on the basis of duplex findings alone[4,5]. However, angiography provides visualization of the aortic arch, distal carotid arteries and intracerebral circulation, information not available from duplex.

The principal diagnostic guidelines in the management of carotid artery disease have been based on angiographic criteria[1,2] and it has been the practice in this unit to obtain carotid angiograms on all patients being considered for endarterectomy. This study compares the findings of angiography with those of duplex imaging in 100 consecutive patients with carotid artery disease and assesses the influence of angiography on surgical management.

Patients and methods

Between July 1992 and December 1994, 100 consecutive symptomatic patients (amaurosis fugax 24, transient ischaemic attack 38 and established stroke 38) had colour-coded duplex imaging (Toshiba FFH 140A and 270A, 5–7.5-MHz probes) and arch angiography (selective carotid injection, digital subtraction and two projections). Criteria for performing angiography were history of a focal cerebral event related to the carotid artery and duplex evidence of a tight stenosis or ulcerated plaque. Duplex scans were only repeated on admission for angiography if there was a delay between clinic assessment and angiography. There was a median delay of 3 (range 0–12) weeks between duplex imaging and angiography.

Median age of the 100 patients was 66 (range 42–84) years and 71 were men. Atherosclerotic risk factors included ischaemic heart disease (24 patients), hypertension (48), hyperlipidaemia (15), smoking (64) and diabetes mellitus (seven). At presentation, the majority of patients were taking aspirin (78), and a small number were receiving warfarin (three) or dipyridamole (two).

The degree of internal carotid artery stenosis was defined on duplex using peak systolic velocity at the site of maximal stenosis in addition to anatomical information from colour-coded B mode ultrasonography[6]. Angiographic degree of stenosis was estimated by measuring the degree of reduction of luminal diameter at the site of maximal stenosis, having assessed both projections, as in the European Carotid Surgery Trial[2] (*Fig. 1*). For the purpose of comparison, internal carotid disease was divided into less than 30 per cent, 30–69 per cent, 70–99 per cent or occlusion. Angiograms were also assessed for evidence of arch or intracerebral disease which would affect clinical management

Results

Colour-coded duplex imaging of the symptomatic carotid artery revealed internal carotid artery stenosis of less than 70 per cent in five patients, greater than 70 per cent in 90 and occlusion in four. In one patient it was difficult to establish the degree of internal carotid stenosis because of a heavily calcified plaque at the carotid bifurcation.

Comparison of colour-coded duplex imaging and angiography (Table 1)

Angiography confirmed duplex definition of degree of internal carotid stenosis in 95 symptomatic carotid arteries (stenosis 30–69 per cent, three; stenosis 70–99 per cent, 88; occlusion, four). In one patient duplex failed to image the origin of the internal carotid artery, while angiography showed diffuse internal carotid disease, and in four patients there was a significant variation in the degree of stenosis measured by the two techniques (*Table 2*). In

---

Presented to The Vascular Surgery Society of Great Britain and Ireland, in London, UK, November 1995
Paper accepted 7 December 1995

one patient angiography demonstrated an anterior communicating artery aneurysm; no significant arch lesions were identified.

Specifically with respect to differentiating 70–99 per cent stenosis from less than 70 per cent stenosis or occlusion in both symptomatic and asymptomatic carotid arteries, duplex had a sensitivity of 98 per cent, specificity 96 per cent, positive predictive value 96 per cent, negative predictive value 98 per cent and an accuracy of 97 per cent compared with an angiographic standard. There was no significant difference in the findings of duplex and angiography in these groups ($\chi^2 = 1{\cdot}22$, 1 d.f., $P = 0{\cdot}25$, McNemar's test with continuity correction).

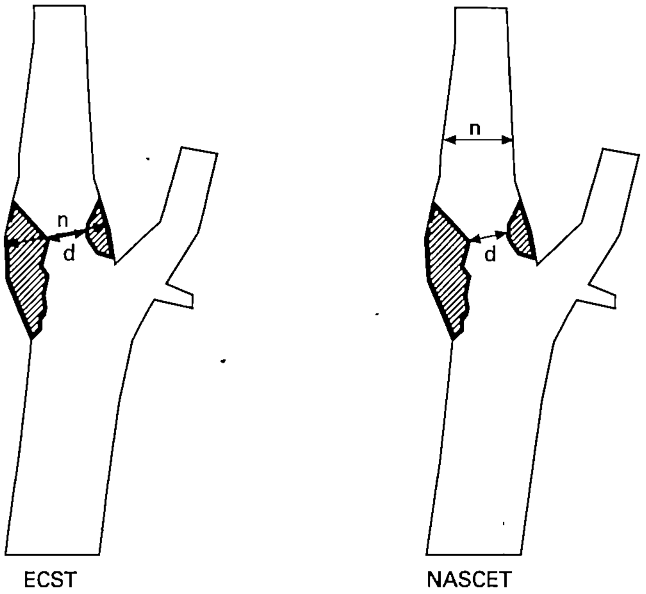

Fig. 1 Angiographic measurement of degree of internal carotid stenosis used in the European Carotid Surgery Trial (ECST) and North American Symptomatic Carotid Endarterectomy Trial (NASCET). In ECST (and this study) the residual lumen (d) was compared with the expected normal lumen at that site (n). In NASCET the residual lumen (d) was compared with the diameter of the distal normal internal carotid artery above (n). Percentage stenosis was calculated as 1 – d/n × 100

Table 1 Comparison of angiographic and colour-flow duplex definition of carotid stenoses

Stenosis (%) on duplex	Stenosis (%) on angiography			
	0–29	30–69	70–99	100
0–29	47	5	0	0
30–69	1	18	2	0
70–99	0	2	103	2
100	0	0	0	18

Effect of investigations on clinical management

Ninety patients (90 per cent) underwent carotid endarterectomy. Reasons for conservative treatment in the other ten included angiographic evidence of less than 70 per cent stenosis plus no symptoms for over 6 months (four), occlusion (four), cerebral artery aneurysm (one) and diffuse disease unsuitable for endarterectomy (one). One patient died following angiography. A 79-year-old woman developed mesenteric ischaemia and subsequently died in the intensive care unit. There were no neurological complications. Findings on angiography could be considered to have revised decisions made after duplex findings alone in only four cases: the patient in whom an anterior communicating aneurysm was discovered, one in whom it was difficult to visualize the origin of the internal carotid and the two patients in whom less than 70 per cent stenosis was revealed. However, in the latter two patients, the fact that no symptoms had been experienced for over 6 months was more relevant than the differences in duplex and angiography.

Postoperative complications included stroke (one patient), transient ischaemic attack (two) and hypoglossal neuropraxia (one). The stroke and hypoglossal palsy had both resolved in 3 months' follow-up.

Discussion

The benefits of endarterectomy in symptomatic patients with high-grade carotid stenosis are clear. The North American trial[1] showed an absolute reduction of 17 per cent in the risk of ipsilateral stroke for symptomatic patients with 70–99 per cent stenosis. The European trial[2] showed a less substantial, but still significant, reduction in stroke risk for 70–99 per cent stenosis. The benefits for patients with less severe stenoses are unknown[3].

Both trials divided groups on the basis of angiographically defined degree of stenosis. The North American Symptomatic Carotid Trial (NASCET) compared the diameter of the stenotic lumen with that of the normal artery beyond the bulb whereas the European trial compared the diameter of the stenotic lumen with that of the presumed outline of the carotid bulb (*Fig. 1*). Both methods have been shown to underestimate the actual anatomical stenosis as measured by planimetric analysis of endarterectomy specimens[7]. Similarly, the European and North American methods and duplex all give significantly different results for identical stenoses[7].

Table 2 Patients considered for surgery where angiography and duplex findings were significantly different

Patient no.	Age	Sex	Indication	Duplex (% stenosis)	Angiogram (% stenosis)	Delay between scan and angiogram (weeks)
1	68	F	Amaurosis fugax	80	60	8
2	65	F	TIA	70	60	<1
3	54	M	Stroke	60	85	<1
4	61	M	Stroke	50	90	12
5	68	F	TIA	>90	Cerebral aneurysm	8
6	72	F	Stroke	Unclear	50	<1

TIA, transient ischaemic attack

Duplex provides the most accurate measurement compared with the excised specimen[7,8]. Other techniques such as magnetic resonance angiography (MRA) and spiral computed tomography (CT) are increasingly being employed[9].

In consideration of the best method of carotid assessment, important factors are accuracy of the investigation, morbidity of the technique, economic cost and effect on clinical management. In this study angiography has been used as the 'gold standard' since trials establishing the selection criteria for carotid endarterectomy have been based on angiographic measurements[1,2,10]. There was good agreement between angiography and duplex in defining degree of stenosis. Considering all 198 carotid arteries visualized (in 100 patients) by duplex the positive and negative predictive values were 96 and 98 per cent respectively for 70–99 per cent stenoses. There was no statistical difference between angiography and duplex in differentiating 70–99 per cent stenosis from less than 70 per cent stenosis or occlusion ($P = 0{\cdot}25$). Duplex and angiography placed 94 per cent of symptomatic stenoses in the same category. Given the delay in performing angiography, of up to 12 weeks, and improvements in imaging technology since 1992, a prospective study might now show these differences to be even smaller. Other studies have yielded similar results[11,12]. Mattos *et al.*[12] reported a sensitivity of 98 per cent and a specificity of 90 per cent for duplex imaging compared with angiography in defining a stenosis of greater than 50 per cent. While peak systolic velocity criteria have been employed in this study, some publications have proposed other methods. Moneta *et al.*[13] assessed a number of duplex methods of defining 70–99 per cent stenosis compared with the NASCET angiographic method and concluded that the internal carotid to common carotid peak systolic ratio gave the highest accuracy.

More important than comparison of measurements is the effect of these investigations on clinical management. While at present a 70 per cent stenosis in a symptomatic patient may be taken as a basis on which to offer carotid endarterectomy, this may change with further research. Of the ten patients not offered surgery relevant findings from angiography were a cerebral aneurysm, and a stenosis of less than 70 per cent in two patients. The importance of the cerebral aneurysm as a contraindication to carotid endarterectomy is arguable. Other studies support the finding that angiography rarely alters patient management; Matos *et al.*[12] found angiography affected clinical management in only 4 per cent of patients. Similarly, Dawson *et al.*[14], in assessing 94 carotid stenoses by angiography and duplex, found the latter to be diagnostic in 93 per cent of patients.

The risk of disabling stroke and death following arch angiography has been estimated as 1 and 0·06 per cent respectively[15]. The single death in this study emphasizes the significant risk of angiography, especially in light of the low overall complication rate following endarterectomy (1 per cent transient stroke in this study). While none of the patients undergoing angiography in this study suffered neurological complications, the recently published Asymptomatic Carotid Atherosclerosis Study[16] reported a stroke rate of 1·2 per cent following angiography. In comparison, duplex imaging is associated with no known morbidity, and is repeatable and cheap.

Factors other than the degree of internal carotid artery stenosis are important in determining the risk of stroke. Increasing evidence is now accumulating about the importance of plaque morphology, e.g. lipid content, continuity of fibrous cap and surface ulceration[17]. This information may affect the need for other methods of carotid assessment such as MRA. However, duplex appears to be well placed to provide accurate plaque imaging.

While duplex scanning has definite advantages over angiography with respect to associated morbidity and cost, there are instances when colour duplex assessment may be inadequate. A number of publications have reported difficulty in differentiating occlusion and tight stenosis[14]. Recent improvements in technology may have overcome this problem; Mattos *et al.*[18] reported 100 per cent accuracy of colour-coded duplex in defining carotid occlusion compared with angiography. The accuracy of duplex in defining occlusion may be improved by use of contrast enhancement[19]. Rarely, visualization of the carotid bifurcation can be hampered by a heavily calcified plaque[14], as in one patient in this study.

In most cases duplex imaging can now be used alone as an accurate, safe and cheap alternative to angiography. When duplex assessment is technically difficult arch angiography should be performed. In the future, spiral CT or MRA may be a safer alternative. Local audit of results is advised to confirm the applicability of these findings to other vascular laboratories.

Hyperhomocysteinaemia is an independent risk factor for the early development of arterial disease. Homocysteine and cardiovascular risk factors were assessed in 41 young and 25 older patients with vascular disease. As homocysteine may act by the generation of free radicals, total antioxidant capacity was measured. Hyperhomocysteinaemia was found in 29 per cent of patients but there was no difference between young and older patients. Homocysteine level was unrelated to other cardiovascular risk factors. Young age, diabetes and hyperhomocysteinaemia were independent risk factors for the failure of vascular procedures ($P = 0{\cdot}006$). Patients with hyperhomocysteinaemia had raised total antioxidant capacity. The potential of identifying and treating a subgroup of patients with a poor prognosis deserves further study.

Hyperhomocysteinaemia is a recently identified independent risk factor for the early development and progression of atherosclerotic lesions[1–3]. The congenital disorder homocysteinuria is associated with very high levels (greater than 100 μmol/l) of the thiol-containing amino acid homocysteine[4]. This condition is also associated with ocular and skeletal deformities, and death from severe atheromatous disease at an early age. Classically, homocysteinuria results from a homozygous enzyme deficiency of cystathionine β-synthase which irreversibly converts homocysteine to cystathionine[5]; patients heterozygous for this genetic disorder show moderately raised levels of plasma homocysteine. A number of congenital disorders of enzymes involved in homocysteine metabolism have also been identified as causing hyperhomocysteinaemia[5]. Vitamins B_6, B_{12} and folate are cofactors for homocysteine metabolism and acquired deficiencies may also result in mild hyperhomocysteinaemia[2,5–8]. A raised level of homocysteine has been proposed as a potentially treatable risk factor for the development of atherosclerotic disease at an early age[9,10].

The aims of this study were, first, to compare levels of serum homocysteine in a group of young patients undergoing vascular intervention for peripheral vascular disease with those of a group of older patients undergoing similar procedures and, second, to investigate the influence of homocysteine on the failure of peripheral vascular intervention. It is postulated that homocysteine may cause endothelial cell injury via a direct toxic effect and/or via generation of free radicals[11,12]. Free radicals are antagonized *in vivo* by antioxidants such as urate, α-tocopherol and glutathione. The association between homocysteine and serum total antioxidant capacity was, therefore, also investigated to look for evidence of depletion of antioxidants as a result of increased free radical generation.

Patients and methods

Using computerized databases, 55 patients were identified who had undergone either angioplasty or vascular surgery for lower-limb arterial disease at age 45 years or less at the time of attempted revascularization. Each patient was matched with an older control who had undergone a similar vascular intervention at approximately the same time. Of 83 surviving patients, 66 (three women) agreed to attend for outpatient review and are the subject of this study. The remaining 17 surviving patients were contacted but were either unwilling to attend or had moved out of the area.

Of the patients studied, 41 were young (median age 43 years) and 25 were older (median age 68 years) at the time of the original vascular intervention. Twenty-seven were current and 39 were ex-smokers. The procedures performed on the 66 patients are shown in *Table 1*; 11 were diabetic and 12 were hypertensive. Two patients had acute ischaemia, nine had critically ischaemic limbs and 55 were claudicants. All patients were thought to have atherosclerotic peripheral vascular disease on the basis of clinical findings and arteriography.

Case notes of all patients were reviewed. Failure of the initial revascularization procedure was diagnosed when preoperative symptoms returned with a fall in ankle:brachial pressure index to within 0·15 of the preoperative value. Requirement for a further revascularization procedure on the same limb or for amputation also indicated failure of the initial vascular procedure. All patients were followed up regularly in a vascular studies unit.

A clinical history was taken and ankle pressures determined. Carbon monoxide levels in expired air were measured using a Bedfont micro smokerlyzer (Bedfont Scientific, Upchurch, UK). Venous blood was taken from fasted patients, centrifuged, and a serum sample frozen at −70°C within 10 min. Full blood count, clotting screen, and measurements of plasma viscosity and serum fibrinogen level were carried out. Liver function tests were performed, serum levels of creatinine, urate, cholesterol and triglyceride were measured. Three patients were receiving warfarin therapy at the time of study, in one case for known

protein C deficiency. No patient was taking B_{12} or folic acid supplements.

Frozen serum samples were thawed to perform homocysteine and antioxidant assays. Homocysteine levels were measured by high-performance liquid chromatography (HPLC)[13,14]. Total serum concentrations were measured by first liberating homocysteine from protein and mixed disulphides. Liberated thiols were then derivatized with a fluorogenic reagent and 20 μl of the sample assayed by reverse-phase HPLC. Initial studies on 46 healthy laboratory staff (30 men, 16 women, age range 21–63 years) found a mean serum homocysteine concentration of 12·2 μmol/l for men and 10·4 μmol/l for women (95th centile values 18·0 μmol/l and 13·6 μmol/l respectively).

Total antioxidant capacity was determined using an enhanced chemiluminescent assay[15]. This involved a steady production of free radicals that react with luminol to cause light emission which was measured by a luminometer. Added antioxidants in serum cause a temporary quenching of free radical production, detectable as a reduction in light emission. High levels of antioxidants cause a more prolonged reduction in light emission. The method is calibrated using the synthetic tocopherol analogue Trolox (6-hydroxy-2,5,7,8-tetramethylchroma-2-carboxylic acid; Aldrich Chemical, Gillingham, UK).

Results

Patients aged 45 years or less represented 4·5 per cent of all those having lower-limb arteriography and 2·9 per cent of patients undergoing lower-limb revascularization operations. At the time of study, five young patients and 22 older controls had died, generally of cardiovascular disease. The duration of clinical and haemodynamic improvement following the initial revascularization procedure is shown in *Fig. 1* for the 66 patients studied. Four patients required amputation because of failure of vascular intervention; none of them had high levels of homocysteine. Of nine early failures within the first month, two were due to technical problems at angioplasty but in seven patients thrombosis of initially patent grafts or radiologically successful dilatations occurred. Four of these nine patients had hyperhomocysteinaemia. Nine patients had intermediate failure between 1 and 12 months after the procedure. In three of these, graft occlusion occurred because of intimal hyperplasia noted at revisional surgery. Five angioplasty sites restenosed and stenosis of the donor limb to a femorofemoral crossover graft occurred in one patient. Two of the nine patients with intermediate failure had hyperhomocysteinaemia. There were six late failures over a year after the original procedure. In two patients this resulted from disease progression and in three was due to disease recurrence at the site of a previous angioplasty. One patient had a late vein graft stenosis. Two patients with late failure had hyperhomocysteinaemia.

Homocysteine levels greater than the 95th centile for a normal healthy population were considered to be significantly raised. Levels in young and old patients are shown in *Fig. 2*. The incidence of hyperhomocysteinaemia was 29 per cent in all patients studied. There was no difference in homocysteine levels found in young and old patients ($P = 0{\cdot}46$, unpaired t test). Patients with hyperhomocysteinaemia had significantly higher creatinine and urate levels, and total antioxidant capacity than those with normal homocysteine levels. The prevalence of other cardiovascular risk factors was similar in patients with normal and raised levels of serum homocysteine (*Table 2*).

Table 2 Cardiovascular risk factors and related parameters in patients with normal and raised homocysteine levels

	Patients with normal homocysteine level	Patients with homocysteine level above above 95th centile	P*
No. of patients	47	19	
Serum cholesterol (mmol/l)	6·34	6·22	0·73
Serum triglycerides (mmol/l)	2·19	2·57	0·33
Serum fibrinogen (g/l)	4·21	4·34	0·71
Plasma viscosity (mPa/s)	1·72	1·74	0·44
Carboxyhaemoglobin (%)	1·72	1·93	0·72
White cell count ($\times 10^9$/l)	7·64	7·69	0·95
Serum urate (μmol/l)	357	456	0·001
Serum total antioxidant capacity (μmol/l)	475	566	0·007
Serum creatinine (μmol/l)	101	116	0·007

Values are mean. *Unpaired t test

Factors influencing the survival of the initial vascular procedure for all 66 patients undergoing blood tests were studied using multiple logistic regression. A Weibull survival model was assumed and the influence of age, diabetes, hypertension and biochemical variables on the survival of vascular procedures studied. Young age at intervention, diabetes and hyperhomocysteinaemia were significant, independent risk factors for the failure of vascular intervention ($P = 0{\cdot}006$, log rank test).

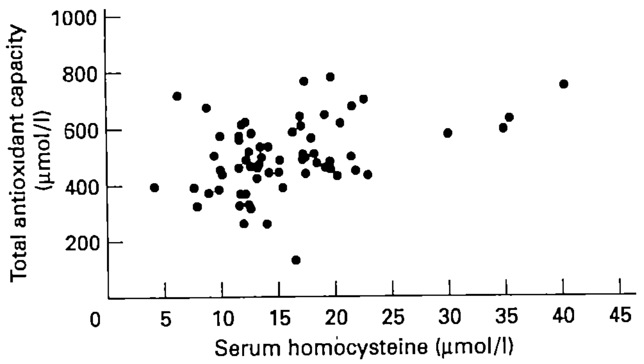

Fig. 3 Relationship between serum homocysteine and total antioxidant capacity ($r = 0{\cdot}37$, $P < 0{\cdot}01$)

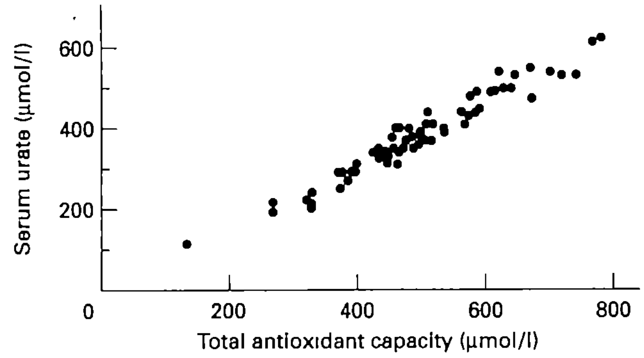

Fig. 4 Relationship between total antioxidant capacity and serum urate level ($r = 0{\cdot}97$)

The relationship between serum homocysteine level and total serum antioxidant capacity is shown in *Fig. 3*. Linear regression analysis shows a positive correlation between serum homocysteine and total antioxidant capacity ($r = 0{\cdot}37$, $P < 0{\cdot}01$).

The relationship between urate, a known antioxidant, and total antioxidant capacity, measured by the enhanced chemiluminescent assay, is shown in *Fig. 4*. Linear regression analysis shows that the correlation between urate and total antioxidant capacity is close ($r = 0{\cdot}97$). Urate levels may be raised by renal impairment and a positive association was found between serum urate and creatinine levels ($r = 0{\cdot}54$, $P < 0{\cdot}001$).

Discussion

The assay for direct measurement of total homocysteine proved to be robust, with good repeatability and accuracy[14]. Raised levels of homocysteine have been reported in patients developing premature arterial disease and screening for this abnormality has been advocated in young patients with vascular disease[10]. The upper 95th centile values established for healthy women and men were compatible with those of previous studies[1,2,7,14,16]. Boers *et al.*[17] found that 30 per cent of patients aged 50 or less with symptoms of cerebrovascular or peripheral arterial disease had raised peak levels of homocysteine after a methionine loading test. The reported incidence of hyperhomocysteinaemia ranges from 13 to 38 per cent[1–3,6,9,16,18]. The present finding of hyperhomocysteinaemia in 29 per cent of patients studied is thus consistent with previous reports. Taylor and colleagues[1] reported that raised levels of homocysteine, in a consecutive series of arteriopaths, were not related to age, supporting the findings in the present study[1]. However, Brattstrom *et al.*[8] and Molgaard and co-workers[2] reported that homocysteine levels tended to rise with increasing age.

Homocysteine has been shown previously to be associated with the development and progression of lower-limb arterial disease[1]. This study found that hyperhomocysteinaemia is an independent risk factor for the failure of vascular intervention. Furthermore, there was no significant difference in the levels of other known cardiovascular risk factors for patients with normal or raised levels of homocysteine, in agreement with previous findings[1,2,8,16]. Hyperhomocysteinaemia was found in patients with early failure due to thrombosis, in intermediate graft failure resulting from the development of vein graft stenoses, and in late failures due to progression of atheroslerotic disease.

Although the development of atherosclerotic lesions and the failure of peripheral revascularization procedures are pathologically different processes, there are similarities[19,20]. Endothelial cell injury may underlie both processes and may be caused by raised homocysteine levels. The pathogenesis associated with the adverse effects of homocysteine are unknown; indeed a direct causal relationship between hyperhomocysteinaemia and atherosclerosis has not been conclusively demonstrated *in vivo*. Patients with hyperhomocysteinaemia had higher creatinine levels than those with normal homocysteine levels. Brattstrom *et al.*[8] also found that serum homocysteine concentration correlated with creatinine level and postulated that impaired renal function may contribute to mild hyperhomocysteinaemia. However, only 13 of the patients undergoing blood tests had a serum creatinine level greater than 120 μmol/l.

It was surprising to find a weak positive correlation between serum total antioxidant capacity and homocysteine level in this study. If homocysteine exerts its pathological effects via the generation of free radicals, high homocysteine level might be expected to be associated with low total antioxidant capacity. However, both mild hyperhomocysteinaemia and raised serum urate (a known antioxidant) may result from renal impairment. Perhaps patients with advanced arterial lesions have a mild degree of renal impairment contributing to hyperhomocysteinaemia and raised urate, and thus antioxidant, levels. The total antioxidant capacity assay only measures aqueous antioxidants and may not relate to the antioxidant conditions operative *in vivo*. Lipid-soluble antioxidants such as α-tocopherol, present in cell membranes to prevent lipid peroxidation, may be important *in vivo* but are not measured by the technique.

Starkebaum and Harlan[21] reported that cultured endothelial cells were injured by hydrogen peroxide generated by copper-catalysed oxidation of homocysteine. Blom *et al.*[22] found that homocysteine levels were not related to malondialdehyde and concluded that lipid peroxidation was not significant in hyperhomocysteinaemia. Stamler and colleagues[23] postulated that homocysteine may react *in vivo* with nitric oxide to produce a compound with vasodilatory and antithrombotic properties. In summary, the pathogenesis of the apparently adverse effects of homocysteine on arterial disease remains unclear.

A retrospective review of 29 patients who had an anoplasty using the sliding House advancement flap was carried out to evaluate the efficacy and safety of this new technique. Long-term symptom relief and late complications were determined by telephone interview. Indications for anoplasty were: stenosis (21 cases), ectropion (four), Bowen's disease (two), keyhole deformity (two) and perineal fistula (one). A single House flap was performed in most patients, but eight required multiple flaps. Lateral internal sphincterotomy was performed concomitantly in 16 of 21 patients with anal stenosis. Postoperative complications included donor-site separation (14), urinary retention (eight) and sepsis (four). At a median follow-up of 28 months, 26 of 29 patients had improved and 24 were completely satisfied. House flap anoplasty can be used to correct many anoderm deficiencies with a high rate of success and patient satisfaction.

Anal stenosis and ectropion are manifestations of a deficiency of anoderm. This usually follows a previous haemorrhoidectomy, ileal pouch–anal anastomosis, correction of an imperforate anus or excision of a premalignant or malignant perianal skin lesion. A deficiency of anoderm may be obvious immediately, for example, after excision of extensive Bowen's disease, or it may become apparent after many years, for example, when anal stenosis follows haemorrhoidectomy. Several flap procedures have been devised to correct anal stenosis, ectropion and other conditions associated with a deficiency of anoderm[1–16].

Simple random flaps receive their blood supply through a skin bridge to the dermal and subdermal vascular plexus in the flap. Examples of random advancement flaps include the Y–V[2,3] and mucosal advancement anoplasties[4]. More extensive random rotational flaps include the C anoplasty[5] for unilateral coverage and the S anoplasty[6] for complete lining of the anal canal.

Random full-thickness sliding advancement flaps lack a skin bridge and receive blood supply through unnamed vessels extending through a fatty pedicle from the underlying muscle. These include the V–Y anoplasty[7], the rectangular graft of Sarner[8], the U-shaped island flap[10] and the newly described 'House' advancement pedicle flap[11]. Recently, the authors have used the House advancement pedicle flap for all patients with anal stenosis, ectropion and other deficiencies of anoderm because its design and construction combine some of the best features of the other flap techniques. This study reviews the indications for, and operative results, postoperative complications and long-term function of, House flap anoplasty.

Patients and methods

The notes of 29 consecutive patients who underwent House flap anoplasty between December 1990 and April 1994 were reviewed Data collected included age, sex, indications for surgery and immediate postoperative complications. Long-term relief of symptoms, late complications and overall satisfaction were determined by note review and telephone interview with each patient in July 1994.

House flap anoplasty was performed as previously described[11]. Preoperative preparation consisted of a small enema but full mechanical bowel preparation was used when construction of multiple House flaps was anticipated. Perioperative antibiotics were not used. The patient was placed in the prone jack-knife position, a nasal speculum or small Ferguson retractor was placed in the anus and a longitudinal incision made in the right or left lateral position from the dentate line to the end of the stricture. Proximal and distal incisions were made perpendicular to the initial longitudinal incision (*Fig. 1*). Undermining the tissue edges of the longitudinal incision created a rectangular-shaped defect (*Fig 2*). A partial lateral internal sphincterotomy was performed if the internal sphincter muscle seemed to contribute to the stenosis. The 'walls' and 'roof' of the House flap were then incised, and the flap mobilized by dissection into the ischiorectal fat, avoiding undermining of the flap. When the flap could be easily advanced into the anal canal, it was sutured in place with 3/0 absorbable suture (*Fig. 3*). Patients with ectropion had it excised, and the resulting defect was filled with one or more House flaps. Stool softeners and sitz baths were prescribed after operation

Indications

House flap anoplasty was performed on 30 occasions in 29 patients over 3·5 years. Twenty women and nine men had the procedure, with a mean age of 60 (range 25–82) years. The indications for anoplasty are shown in *Table 1.* Stenosis most often occurred due to previous haemorrhoidectomy (16 cases) or ileal pouch–anal anastomosis (two). Ectropion occurred as a result of a haemorrhoidectomy, ileal pouch–anal anastomosis, vulvectomy with excision of the perianal skin, or correction of an imperforate anus.

The number of House flaps and concomitant use of a lateral internal sphincterotomy varied with the indications and findings at operation. Lateral internal sphincterotomy was added to 16 of 21 House flap procedures performed for anal stenosis. Ectropion and Bowen's disease usually required multiple House advancement flaps, and sphincterotomy was not performed. Multiple-quadrant flaps were placed diagonally to keep the incisions away from the midline.

Results

Median postoperative stay was 1 (range 1–11) days. The length of stay depended on the number of advancement

flaps performed. The two patients who underwent four-quadrant House flaps stayed in hospital for 7 and 11 days respectively.

Although there was no flap necrosis, recurrent stenosis, or recurrent ectropion, 20 patients had minor complications in the immediate postoperative period (*Table 2*). Donor-site wound separations were small and usually completely healed within 2 weeks. Postoperative septic complications included two urinary tract infections, one perianal streptococcal cellulitis, one perianal *Candida* infection and one *Clostridium difficile* colitis. One House flap retracted 5 days after operation, and required reoperation and replacement of the flap into the anal canal. Intermittent flatus and liquid incontinence developed in the two patients with Bowen's disease who required multiple House flaps. An unsuspected obstetric injury to both the internal and external anal sphincter was identified by postoperative transanal ultrasonography in one of these patients. Finally, House flap anoplasty failed to correct a perineal fistula in one patient.

Table 1 Indications for House flap anoplasty

Indication	No. of cases
Anal stenosis	21
Ectropion	4
Bowen's disease	2
Keyhole deformity	2
Perineal fistula	1

Table 2 Postoperative complications after House flap anoplasty

Complication	No. of cases
Donor site separation	14
Urinary retention	8
Septic complications	5
Incontinence (flatus and liquid)	2
Flap retraction	1

At a median follow-up of 28 (range 3–43) months, 26 of 29 patients had relief of preoperative symptoms and were able to discontinue stool softeners, laxatives and enemas after House flap advancement anoplasty. None of the patients with ectropion or keyhole deformity complained of further seepage or leakage after operation. Intermittent incontinence to both flatus and fluid persisted at 12 and 32 months after surgery in the two patients who underwent multiple House flaps for Bowen's disease.

Overall, 24 of 29 patients were satisfied with House flap anoplasty. Reasons for dissatisfaction in five patients included persistent pelvic pain not associated with the operation, occasional pain with defaecation despite relief of stenosis, stool urgency that did not occur after the operation, but after radiation therapy to the pelvis, severe pruritus in one of the scars after a four-quadrant House flap and recurrent perineal fistula after attempted House flap repair.

Discussion

The House advancement pedicle flap has been used for 29 consecutive patients with anal stenosis, ectropion and other deficiencies of anoderm. It combines the V–Y anoplasty[7] wound closure and Sarner's rectangular-sliding advancement flap[8]. It provides a long full-thickness section of anoderm based on vessels perforating from the underlying external anal sphincter. The rectangular base of the House flap is advanced proximally to provide coverage for the entire length of the anal canal. The outer triangular cut allows the donor site to be closed primarily in a V–Y fashion. Many high or long stenoses previously treated with multiple sphincterotomies, anal dilatation or extensive flap procedures may be more safely and simply treated by the House flap.

In this review, the House flap procedure successfully treated the primary problem in 26 of 29 patients. At a median follow-up of 28 months, 24 patients were completely satisfied. In patients with anal stenosis or ectropion treated with a diamond island flap, Pearl *et al.*[10] reported a good-to-excellent result in 92 per cent, and Pidala and colleagues[12] described an improvement rate of 91 per cent. Milsom and Mazier[13] noted good results in 90 per cent of patients undergoing a V–Y anoplasty or Y–V anoplasty for anal stenosis. In these three other studies, however, the type of flap varied depending on the particular diagnosis and circumstance. In the present series a similar success rate was achieved using only the House flap anoplasty for stenosis, ectropion and other conditions requiring new anoderm.

Few complications of the various anoplasty techniques have been reported. Khubchandani[14] reported a wound separation rate of 12 per cent after modified Martin anoplasty for stenosis in 41 patients, but did not describe any postoperative urinary tract problems. In other series, the perianal skin or donor-site wounds were left open, and consequently all patients required postoperative wound care. Both Pidala *et al.*[12] and Gingold and coworkers[2] closed the donor sites and noted wound separation rates of 18 and 36 per cent respectively. These series also reported urinary tract complications in 3–7 per cent of patients. On the basis of the published literature, the overall complication rate in the present series of 66 per cent, which included a wound separation rate of 47 per cent and a postoperative bladder catheterization rate of 27 per cent, seems to be high. These patients, however, differed from those in other studies in which a single flap for anal stenosis or ectropion was performed. In the series described here, five of 30 House flaps were done for indications other than stenosis or ectropion and eight were multiple. Multiple-quadrant House flaps were associated with a higher morbidity than a single flap. Other studies with limited follow-up reported no complications[3–5,7,9,13,15,16]. The present detailed study reporting complications in patients who were followed long term, emphasizes the need to inform patients before operation about potential wound, urinary tract and septic complications, especially when multiple flaps are anticipated. In addition, preoperative anorectal manometry and transanal ultrasonographic studies are now performed on women who may require multiple House flaps to detect occult sphincter injury.

House flap anoplasty is a simple, safe method to correct all types of anoderm deficiencies with a high rate of success and patient satisfaction. Its construction and design combine some of the best features of other flap repairs. It can be used in nearly any case in which there is a deficiency of anoderm.

Short note

p53 Mutations in primary colorectal adenocarcinomas and liver metastases

J. YAO, H.-S. GOH and D. R. SMITH

Department of Colorectal Surgery, Singapore General Hospital, Outram Road, Singapore 169608
Correspondence to. Dr D. R. Smith

Point mutation of the p53 tumour suppressor gene is found in approximately 50 per cent of colorectal adenocarcinomas, with 98 per cent of point mutations falling within a 600-base-pair region of the messenger RNA, corresponding roughly to exons five to nine[1]. The majority of these point mutations consist of single base substitutions, leading to the incorporation of alternate amino acids in the p53 protein. Single base substitutions leading to non-sense or chain terminating codons are rare, although deletions or insertions leading to frame shift mutations are slightly more common[1]. Point mutation of the p53 tumour suppressor gene in colorectal adenocarcinomas has been shown to be associated with disease dissemination[2] and poor prognosis[3]. Metastatic disease is the primary cause of death in patients with colorectal cancer. The status of the p53 gene in metastatic liver deposits was therefore examined.

Materials and methods

Eight fresh liver secondary tumours were available for analysis. Each was histologically defined as a metastatic lesion from a primary colorectal adenocarcinoma. In six cases the primary tumour was also available for analysis. Point mutations of the p53 gene were detected initially by single stranded conformational polymorphisms, and mutations were then characterized by double stranded polymerase chain reaction cycle sequencing using a panel of primers as described elsewhere[4].

Results

Point mutations of the p53 gene were detected in seven of eight liver metastases tested. The remaining sample contained a deletion of one allele corresponding to codons 174–183 (*Table 1*). In the six cases in which the primary colorectal adenocarcinoma was also available for analysis, point mutations were detected in four samples. In each case where the primary adenocarcinoma contained a point mutation, the same point mutation was detected in the liver metastasis (*Table 1*).

Discussion

All metastatic liver deposits in this study evinced alterations of the p53 tumour suppressor gene. In seven cases point mutations were detected and in the eighth a deletion in one allele had occurred. These results are consistent with a recent report[5] also showing a high rate of p53 point mutation in hepatic metastases: a mutation rate of 77 per cent in metastases compared with 44 per cent in primary colonic adenocarcinomas. The presence of point mutations in the liver secondaries that were not found in the colorectal primary in both studies suggests that metastatic lesions can arise from subpopulations of cells that are not represented in the sample of the primary lesion. Furthermore, the high rate of mutation found in

Table 1 p53 Mutations in eight metastatic liver deposits and six corresponding primary colorectal adenocarcinomas

the liver secondaries in both studies suggests that cells containing mutated p53 genes may demonstrate a selective advantage in establishing metastatic outgrowths. This report provides further evidence that mutation of the p53 tumour suppressor gene is one of the main factors determining behaviour of colorectal adenocarcinomas.

Surgical workshop

Reduction of paraphimosis: a technique based on pathophysiology

V. RAVEENTHIRAN

Department of Surgery, Veer Surendra Sai Medical College, Burla, India

Correspondence to: Dr V Raveenthiran, 68 Seventh Street, Sayee Nagar, Madras 600 092, India

Paraphimosis is a painful condition that requires urgent surgical intervention. This paper describes a simple and effective technique of reduction based on the pathophysiology of the condition.

Surgical technique

Under penile block anaesthesia a tourniquet is applied to the shaft of the penis, proximal to the constricting ring of prepuce. With aseptic precautions a 20-g needle on a 10-ml syringe is thrust into the glans parallel to the urethra (*Fig. 1*). About 3–12 ml of blood is aspirated, depending on the size of the glans, until it collapses completely. The needle is withdrawn and firm squeezing pressure is applied to the glans using the pulp of the first three fingers. While maintaining the pressure, the tourniquet is released and the constricting ring of foreskin is gently reduced over the shrunken glans. Elective circumcision is subsequently performed.

Using this technique four patients with refractory paraphimosis were treated successfully without any complication. No tourniquet was used in the first case, and immediate refilling of the glans prevented effective aspiration. The technique was revised thereafter.

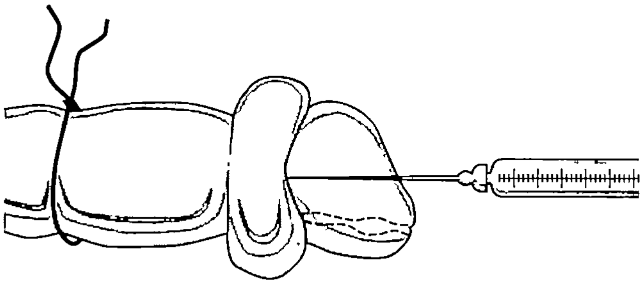

Fig. 1 Position of tourniquet and needle

Paper accepted 19 October 1995

Discussion

Emergency circumcision and dorsal slitting are the most reliable methods of relieving paraphimosis, but the prepuce is often oedematous, friable and infected so that it is technically difficult to achieve a good cosmetic result. Hence many surgeons prefer reduction of paraphimosis, reserving emergency operation for more difficult cases[1].

Whitaker's technique of elongation and squeezing the glans is considered the best method of reduction. Unfortunately this simple manoeuvre frequently fails as the constricting ring is often too tight to allow emptying of the glans. Many authors erroneously believe that the preputial oedema is the cause of irreducibility. Consequently several techniques for reducing the oedema have been proposed. These include puncturing the swollen foreskin[2], injection of hyaluronidase[3], application of hypertonic solutions[4] or ice packs[5], bandaging with a rubber strip, Southey tube drainage and manual massage[2]. It is to be remembered that the oedema is the result and not the cause of irreducibility. Hence attempts to dissipate the oedema are either useless or unnecessary.

In paraphimosis the constricting band of foreskin impedes venous return and causes glandular tumescence, which is the real hindrance for reduction[1]. It is always easier to aspirate blood than to squeeze it past a constricting ring. Aspiration of vascular spaces to produce detumescence is not new; it is an established method in the treatment of priapism[1]. This technique has also been successfully used to relieve strangulation of the penis by metal rings, which is identical to paraphimosis in its pathophysiology[6]. However the application of an aspiration technique in reducing paraphimosis has not been described in the literature. This technique is strongly recommended as a safe, simple and effective method of reducing paraphimosis.

Role of the general surgeon in a British trauma centre

I. M. BAIN, R. M. KIRBY, A. L. COOK*, P. A. OAKLEY† and J. TEMPLETON*

*Departments of Surgery, †Anaesthetics and *Orthopaedic Surgery, North Staffordshire Hospital and School of Postgraduate Medicine, University of Keele, Stoke-on-Trent, UK*

Correspondence to: Mr R. M. Kirby, Department of Surgery (M017), North Staffordshire Hospital, Stoke-on-Trent ST4 6QG, UK

A prospective audit of trauma patients seen or treated by the Department of General Surgery at the North Staffordshire Hospital Trauma Centre has been carried out, examining both the effect of a newly established trauma centre on overall workload and the outcome of patients admitted with severe injury. Trauma comprised approximately 2 per cent of the overall general surgical emergency workload. General surgeons were involved in the assessment of 25 per cent of severely injured patients but overall operated on fewer than 10 per cent of patients in this group. No patient died during the study period as a consequence of missed or inadequately treated intra-abdominal injury. These data suggest that there is insufficient work to justify specialist general surgical trauma surgeons in the UK. When general surgical intervention is required, however, it is usually vital and potentially life-saving.

A report[1] from the Royal College of Surgeons of England in 1988 recommended that certain patients with life-threatening injuries should have the opportunity of transfer to a specialized trauma centre. The report was based largely on the findings of a retrospective study of 1000 deaths from trauma[2] from 11 coroners' districts. This study revealed serious deficiencies in the management of seriously injured patients. Over 30 per cent of hospital deaths in severely injured patients were assessed as being potentially preventable; many non-neurological deaths occurred principally as a result of hypotension with delayed and/or inadequate surgical treatment. Two prospective studies[1,3] confirmed the finding of serious deficiencies in the management of severely injured patients and suggested that there could be survival benefits from sophisticated injury services. The College therefore proposed the instigation of trauma centres on a regional basis with all major surgical facilities on site, providing a 24-h service with surgical, anaesthetic and radiological staff of consultant level, together with their trainees. In July 1991 a pilot trauma centre was established at the North Staffordshire Hospital, Stoke-on-Trent, in a Department of Health study.

The North Staffordshire Hospital is a tertiary centre and is one of only seven hospitals in the UK with all surgical specialties including cardiothoracic surgery and neurosurgery on a single site. It serves a local population of 500 000. The trauma centre acts as a hub of the trauma system, serving a population of almost two million. Injured patients are either transported directly to the trauma centre by the ambulance services (land or air) or transferred from the five local district hospitals within the trauma system.

In North America, where trauma centres are established with improvements in patient management and survival[4,5], severely injured patients are usually admitted under the care of a trauma service, staffed by trauma surgeons, a subspecialty of general surgery. The pattern of trauma seen in most North American trauma centres is different from that in the UK, with a major proportion of admissions having penetrating injuries; for example, only 12 per cent of laparotomies performed at the Atlanta Trauma Center were for blunt trauma[6], compared with the UK where the majority of trauma is blunt. The results of a 1-year audit before the opening of the trauma centre at the North Staffordshire Hospital[7] showed that penetrating injury accounted for less than 5 per cent of all trauma (likewise only 8·9 per cent of patients admitted to the Royal London Hospital via helicopter had stab or gunshot wounds[8]). Although the Department of General Surgery was involved in the planning of the trauma centre, it was decided that there would be no attempt to assume the role of 'trauma surgeon'. Extra consultant posts were created in accident and emergency and anaesthetic departments, but the opening of the trauma centre coincided with changes in the on-call surgical rota involving reduction in the number of on-call junior staff.

The effect of the establishment of the trauma centre system on the work of the general surgeon has been examined both in terms of overall workload and, more specifically, with regard to assessment and operative intervention of severely injured patients. All patients received by the trauma team were studied to exclude those with missed or inappropriately managed abdominal injuries who might otherwise have been seen by a general surgical trauma surgeon.

Patients and methods

The general surgical trauma workload at the North Staffordshire Hospital was compared in the year before the establishment of the trauma centre (April 1989 to April 1990) and for 2 years (April 1992 to April 1994) afterwards.

Data were collected prospectively on every patient received following trauma Information was collected from trauma forms, patient's notes and medical staff. This included demographic data, details of all injuries, the patient's respiratory rate, systolic pressure and Glasgow Coma Scale on admission. The notes were checked for time of arrival at the centre, time of admission to operating theatre, operative details including grade of surgeon, involvement of different surgical teams and eventual outcome. Trauma death was defined as death occurring within 30 days of admission Post-mortem data were collected on all trauma deaths.

Severely injured patients were classified by the following criteria: Injury Severity Score (ISS) greater than 15 and/or a Revised Trauma Score (RTS) of less than 7·84. The ISS is based on the Abbreviated Injury Score devised by the Association for the Advancement of Automotive Medicine of the USA[9]. The

Paper accepted 14 December 1995

RTS was calculated using respiratory rate, systolic blood pressure and Glasgow Coma Scale recorded on arrival at the emergency department at the North Staffordshire Hospital or, in the case of transfers, at the emergency department of the referring hospital

All patients, both seriously and non-seriously injured, were initially assessed in the accident department by the trauma team. The trauma team was led by a resident consultant with a special interest in trauma management from the accident and emergency or anaesthetic departments; it included a registrar from the intensive care unit and a senior house officer or registrar from the accident and emergency department[10]. The senior registrar in general surgery was initially a member of the trauma team, but on review, his or her involvement was usually not necessary. Subsequently the general surgeon has been contacted, based on information relayed either by radio from the accident site itself or by the trauma team after identification or suspicion of injuries found in the primary and secondary surveys as in the Advanced Trauma Life Support (ATLS) protocol[11]. Protocols were established for investigation of the abdomen by diagnostic peritoneal lavage and abdominal ultrasonography. Peritoneal lavage was usually carried out by a general surgeon. Abdominal ultrasonography was performed by a radiologist at the request of either the trauma team leader or the general surgical team. The decision to operate was always made by the general surgeon There were four general surgical teams, each led by two consultants; five of the eight had ATLS training. Each team had one higher surgical trainee (registrar or senior registrar) and one basic surgical trainee.

Results

Overall admissions

The number of trauma admissions to the hospital in the years of the study has not changed significantly (*Table 1*). The number of severely injured patients (both ISS greater than 15 and RTS less than 7·84) increased by about 80 per cent since the introduction of the trauma centre, although the number of transfers from other hospitals did not change significantly. Blunt trauma was the mechanism of injury in over 95 per cent of patients with severe injury; over 50 per cent occurred as a consequence of road traffic accidents.

General surgical trauma admissions

The details of the general surgical overall emergency workload and the work related to trauma admissions are shown in *Fig. 1*. The work relating to severely injured patients is shown in *Fig. 2*. The emergency workload in general surgery remained busy but did not increase. Following establishment of the trauma centre the total number of trauma admissions increased by less than 50 per cent. Operations on all patients with trauma, both severely and non-severely injured, formed only a small proportion (approximately 2 per cent) of the overall emergency general surgical workload. Over 25 per cent of the severely injured were assessed by general surgeons compared with only 16 per cent before establishment of the trauma centre; most of those patients were seen during the initial resuscitation process in the accident and emergency department. In comparison, the majority of the severely injured were seen by the neurosurgical and orthopaedic teams; their involvement remained relatively unchanged. General surgeons were more often involved in the care of patients with penetrating injuries, the majority of which required operative intervention.

The type and number of general surgical operations performed on trauma admissions is shown in *Table 2*. Over 75 per cent of laparotomies on severely injured patients were performed within 4 h of admission (median 2·5 h (range from 10 min to 7 days)). Surgery was usually carried out for unexplained hypotension or suspected intra-abdominal injury detected by either abdominal ultrasonography or diagnostic peritoneal lavage. At most of the laparotomies significant intra-abdominal pathology was found warranting surgical intervention. Injuries found at laparotomy performed after 4 h included bowel injury,

Table 3 Deaths in 1992–1994

	n	Comment
Total no. of deaths	103	Includes two brainstem deaths with non-diagnosed intra-abdominal bleeding
Death during resuscitation	15	Includes one major intra-abdominal bleed and four less severe abdominal injuries
Death on table	2	Major hepatic trauma
Postoperative death	8	Four multisystem failures and four head injuries
Death after general surgical assessment (no general surgical operation)	16	No missed intra-abdominal trauma

delayed splenic rupture, suspected perforated bowel and iatrogenic splenic injury. Two patients had a laparotomy at another hospital before being transferred to the trauma centre for management of non-abdominal injuries.

Deaths

Between April 1992 and March 1994, 15 patients with multiple injuries (mean age 70 years) died during the initial resuscitation, before abdominal injury could be excluded (*Table 3*). Intra-abdominal injuries such as mesenteric tears were found at autopsy in four of these patients, but were not regarded as the primary cause of death. These patients had not been seen by the general surgical team. One patient died despite attempts at resuscitation following transfer from another hospital for neurosurgical assessment; the death was attributed to haemorrhage from splenic and renal injuries. Two patients admitted to the intensive care unit with severe head injuries were noted to have a probable abdominal injury but general surgical involvement was not requested because of brainstem death. In addition to the neurological injury in both patients, liver and splenic injuries and a renal haematoma with free blood were found at autopsy; these injuries were not thought to have contributed significantly to death by the forensic pathologist. Two young patients in extremis were transferred to theatre after initial thoracotomy in the accident and emergency department; both died from unsalvageable liver injuries.

Discussion

Since the establishment of the trauma centre there has not been a significant increase in the number of trauma patients seen in the emergency department, but the number of severely injured patients has increased by about 80 per cent. Although there were more transfers from other hospitals, most of the increase resulted from direct admissions. This reflects, in part, the changed protocols of the ambulance services.

The majority of the severely injured admissions had neurosurgical and/or orthopaedic injuries. General surgeons were involved in the assessment of over 25 per cent of these patients, being called immediately for penetrating injury or haemodynamically unstable patients. Abdominal ultrasonography may have been done before arrival of the general surgical team, but diagnostic peritoneal lavage was not performed before surgical review.

Even though the number of seriously injured patients assessed by general surgeons rose after the establishment of the trauma centre, the requirement for a general surgical opinion about possible abdominal injury and the need for surgery was not as high as expected. A combination of factors may be important: first, the increased experience of the admitting trauma team and, second, the increasing use of diagnostic abdominal ultrasonography in the accident and emergency department to exclude intra-abdominal injury. Experience of these diagnostic modalities for the detection and management of abdominal injuries is presently being evaluated[12].

When general surgical involvement is needed, it is usually because of intra-abdominal bleeding and is therefore required urgently. Fewer than 10 per cent of all the severely injured patients required general surgical operative intervention. Liver and splenic injuries were the commonest cause of intra-abdominal bleeding. A retrospective study of 1000 trauma deaths[2] showed that preventable deaths were due mainly to missed intra-abdominal bleeding rather than inadequate operative management. The decision whether to operate seems to be more important than the actual surgery itself. Negative laparotomies in patients undergoing other procedures concurrently are to be expected and should not be discouraged if significant intra-abdominal injuries are not to be missed. Despite the lack of a general surgeon in the initial trauma team, no patient died from an undiagnosed abdominal injury after admission to the trauma centre.

The low incidence of intra-abdominal and vascular injury reflects the pattern of trauma, which was blunt in over 95 per cent of cases. This was similar to the findings of the first report of the UK Major Trauma Outcome Study[13] and also mirrors the findings of a pre-hospital deaths study in North Staffordshire[14]. Road traffic accidents are the most common mechanism of injury. This differs from many centres in North America where penetrating injuries are common, forming up to 40 per cent of trauma admissions (F. Lewis, personal communication) and over 88 per cent of laparotomies[6]. The need for operative intervention by the trauma surgeon is also low (less than 20 per cent) after blunt trauma in North America. This is a reason given by surgical trainees in North America for the reduced interest in entering a career in trauma surgery[15,16].

The necessity for a trauma surgeon to see all patients with blunt trauma is being questioned in the USA. Recent studies[17–19] have shown that only a small minority of haemodynamically stable patients with blunt trauma require intervention by the trauma team. It was suggested that these patients should be assessed by the emergency room physicians with the trauma surgeon being called only when necessary. This is similar to the policy adopted at the North Staffordshire Trauma Centre.

The question has been posed whether the admitting trauma team should be led by a general surgeon, as initially suggested by the working part of the Royal College of Surgeons. The North Staffordshire model has demonstrated that this is not necessary, especially when general surgeons already have a busy workload. This need not be the only model: at the Royal London Hospital the driving force behind trauma care has been a general surgeon. The trauma team in London is led by a consultant or senior registrar in general surgery working on the principles of the advanced life support system; in the last 4-month interval 38 (58 per cent) of 66 patients admitted via helicopter had surgery[8]. Ten of these had general surgical procedures (details not given) compared with 22 orthopaedic and 15 neurosurgical operations. At the Toronto Trauma Centre[20], which sees a similar pattern of trauma to that in the UK, the team leaders are drawn from any specialty provided they have sufficient trauma training and experience. The team leader, as in North Staffordshire, refers patients to the appropriate specialty in theatre or on the admitting ward.

The lack of a single person in charge of the continued management of multiply injured trauma patients remains a matter of concern[21]. One advantage of trauma surgeons is that they can provide continued care of patients throughout their stay, including the intensive care unit. Residency programmes in trauma surgery therefore include specific intensive care training. In the UK few general surgeons have had specific training in intensive care management.

It may be argued that dealing with less than one severely injured patient requiring surgery per week does not result in the desired increase in operative experience in the management of patients with trauma. Despite the low numbers of patients needing general surgical assessment, working within a trauma system with a fixed resuscitation protocol has proved beneficial in providing surgical trainees with supervised experience of trauma management. To increase numbers further would require a significantly larger catchment area for the trauma centre. If this were to be adopted, a 24-h helicopter service with medical staff would be essential to prevent unacceptable transfer times. This would have considerable financial and staffing implications.

Because of the low overall number of trauma patients seen and the low incidence of general surgical operative intervention despite a two million catchment population, there is no pressing need for a subspecialty of trauma surgery within general surgery. General surgeons in the UK must maintain an active lead in improving trauma care and in carrying out further trauma research.

Correspondence to: Dr T. H. Helbich

In a prospective randomized study, 103 women had stereotactic biopsies performed either in the prone ($n = 51$) or sitting ($n = 52$) position. Questionnaires were administered before and after biopsy, to measure anxiety, pain and subjective experience in all patients. Vasovagal reactions were scored from 0 to 2 according to severity. There was no significant difference between biopsies performed in the sitting or the prone position with regard to overall tolerance. Significantly more patients biopsied in the prone position (15 of 51, 29 per cent) than in the sitting position (seven of 52, 13 per cent) would prefer premedication before a repeat biopsy ($P = 0{\cdot}04$). Of the total patient group, three women fainted, one in the prone position and two others in the sitting position. Breast biopsies performed in the prone or sitting position are equally well tolerated. Somatic reactions such as fainting are not a major problem during breast biopsy; however, attention should be focused on patient care, including information given before the procedure.

During the past decade, several studies have documented the effectiveness of screening mammography in the reduction of deaths from breast cancer[1–3]. The results of these studies have led to a substantial increase in the number of mammograms performed. In the USA, between 13 and 16 million mammographic examinations are performed annually[1,2]. Screening for breast cancer results in at least two benign excisional biopsies for every cancer detected[1,2,4]. The ratio of two benign to one malignant biopsies is the reverse of the current ratio in the UK[3]. The cost of surgical breast biopsy can exceed the cost of screening mammography[1,4,5]. Stereotactic biopsy guided by mammography or ultrasonography is now offered as an alternative diagnostic procedure[4–11]. The cost of stereotactic breast biopsy has been reported to be one-third to one-half that of excisional biopsy. Thus, the cost of breast cancer screening programmes could be reduced substantially[1,5–7].

Breast biopsy is considered safe and is normally well tolerated; however, there is some pain and anxiety associated with the procedure. Considering the high number of biopsies, studies of patient tolerance of the procedure are important. Stereotactic fine-needle aspiration biopsy (FNAB) can be performed with the patient in either the prone or the sitting position[5,8,9].

It is believed that biopsies performed on a seated patient are associated with a higher rate of adverse events, such as fainting, which lead to premature termination of the procedure. The purpose of this study was to compare the two different body positions for breast biopsy with regard to patient tolerance and rate of fainting.

Patients and methods

In this prospective study, 103 consecutive women (mean(s.d.) age 56(11·9) years) who were referred for cytological evaluation of suspicious lesions on mammography between January and September 1994 were assigned randomly to one of two different biopsy units. There were 52 women (mean(s.d.) age 56·6(11·1) years) investigated in the sitting position (Sterotix 2; GE Medical Systems, Milwaukee, Wisconsin, USA) and 51 women (mean(s.d.) age 56·4(12·1) years) assigned to the prone position (TRC-Mammotest, Täby, Sweden).

The details of stereotactic localization and FNAB have been described previously[7,10,11]. Briefly, each lesion was revisualized on the mammographic units. After verification of accurate needle placement, four aspirates were obtained in each case using a 20-G bevelled biopsy needle attached to a syringe. No local anaesthesia was required. All procedures were performed by a single radiologist (G.W.) with experience of more than 1000 FNAB procedures.

Patient questionnaires

Before and after biopsy, the patients were asked to complete the state–anxiety part of the Spielberger State–Trait–Anxiety inventory (range 20–80)[12]. The patients were also asked to complete questionnaires developed specially to assess their attitude toward the procedure before and after the examination (*Tables 1* and *2*). All patients received standard verbal information about the study and were informed that their answers to the questionnaires would not be made available to the clinical staff. In addition, the referring medical staff was not informed about the study to avoid additional information being given and to guarantee normal communication with the patients. Informed consent was obtained from all patients.

Vasovagal reactions

After the procedure all patients were asked if they had experienced a feeling of light-headedness or not. Light-headedness and fainting were scored by one radiologist (G.W.) as follows: 0, no reaction; 1, light-headedness; and 2, fainting causing termination of the procedure.

Statistical methods

Results were expressed as mean(s.d.). All statistical calculations were made using SAS (SAS Institute, Cary, North Carolina, USA)[13]. Group comparisons were done by means of Student's t test or the Mann–Whitney U test as appropriate. Frequency data were analysed with the χ^2 test or Fisher's exact test for small sample sizes. $P < 0{\cdot}05$ was considered significant. All P values were, where applicable, corrected for ties.

Values in parentheses are percentages. *$P = 0{\cdot}04$ *versus* sitting position. There were no other significant differences between patient groups

Results

Before the procedure

Answers to the questionnaire completed before biopsy were not significantly different between the two groups, indicating that they were not biased by the selection method (*Table 2*).

Anxiety ratings

Anxiety ratings before the procedure were not significantly different between the two groups (mean(s.d.) 50·6(10·8) *versus* 51·2(10·3) for prone *versus* sitting position). After FNAB the anxiety levels significantly decreased in all patients ($P = 0{\cdot}0001$); there was no significant difference between the groups (mean(s.d.) 43·5(8·8) *versus* 44·4(8·5) for prone *versus* sitting).

Tolerance of the procedure

Responses to the questionnaire given after the biopsy are shown in *Table 2*. The questionnaires revealed that 39 of 52 patients biopsied in the sitting position and 41 of 51 examined in the prone position rated the examination easy to tolerate, 92 and 96 per cent respectively said they would undergo this examination again, if necessary. Significantly more patients biopsied in the prone position (15 of 51, 29 per cent) than in the sitting position (seven of 52, 13 per cent) stated that they would like to take an anxiolytic before a repeat biopsy procedure ($P = 0{\cdot}04$). The anxiety level, pain rating and motor unrest of patients wishing premedication for a repeat examination were not significantly different from those in patients who did not want premedication for a subsequent biopsy.

Vasovagal reactions

Two patients in the sitting position and one in the prone position fainted, which led to premature termination of the procedure ($\chi^2 = 3{\cdot}42$, 2 d.f., $P = 0{\cdot}18$). Three women had light-headedness in the sitting position. The incidence of adverse events was not significantly different between the two positions with respect to light-headedness and fainting, and for the two reactions combined ($P = 0{\cdot}11$, Fisher's exact test). Comparing the six women with scores of 1 and 2 with those with scores of 0, there was no significant difference in anxiety level, pain rating or response to the questionnaires. Fainting reactions were treated by placing the patient in the supine position and elevating the legs. Three patients with light-headedness needed no more than relaxation in a chair after the procedure. All vasovagal episodes were recognized by the staff and no patient was injured by falling.

Discussion

The results of this study suggest that breast biopsies performed either in the sitting or prone position are equally well tolerated. There were no significant differences between patient groups regarding anxiety, overall tolerance of the procedure and occurrence of vasovagal reactions.

Although breast biopsy is common, little is known about patient attitude toward this procedure performed either in the prone or sitting position[5,8,9]. The success of this invasive procedure is linked closely to the patient's attitude during the investigation. There are a number of factors that influence patient attitude toward a breast biopsy, including anxiety, pain and tolerance.

Various studies describe increased anxiety levels in anticipation of unpleasant situations in connection with medical investigations[14,15]. In this study, a high level of anxiety before the procedure did not influence the frequency of motor unrest, level of pain or rate of fainting, independent of patient position. This finding is supported by others who report that prescan anxiety level does not correlate with prematurely terminated magnetic resonance imaging (MRI) scans[15] and does not lead to an increase in motion artefacts on MRI scans[14]. Thus, a high anxiety level before the investigation does not have a negative influence on patient tolerance of the procedure. Not surprisingly, after the biopsy the anxiety level decreased significantly in both groups.

Pain has an important role in patient attitude during a medical procedure[16–18]. However, pain is not only influenced by the personality and constitution of the patient but also by previous experiences, anxiety, motivation, information, and care and personal interaction between the patient and medical staff[16–20]. In this patient population, 85 per cent of patients in the sitting position and 75 per cent of those in the prone position scored pain as easy to bear during the breast biopsy. Local anaesthesia does not improve patient tolerance in needle localization of the breast[21], although these results are disputed[22]. In addition, it has been shown that complications such as fainting occur independently of the type of interventional procedure performed in the breast either with, or without, use of local anaesthesia[5,8,9–11,21,23]. The finding that pain is not a factor influencing patient tolerance compares favourably with the results of Reynolds *et al.*[21].

It has been argued that biopsy performed in the sitting position increases the number of vasovagal reactions and premature terminations of the procedure. This study identified no significant difference in the occurrence of vasovagal reactions between groups. The six patients with light-headedness and fainting did not differ significantly from the rest of the patient population with regard to their anxiety and pain level as reported in the questionnaires. These results are similar to those reported in the literature for different breast biopsy and interventional techniques (*Table 3*)[5,8,9,21,23]. Even if, with a larger patient population, there should be a difference between the groups, the number of patients who develop problems is so low that as far as clinical management is concerned it is not of great significance.

In this study, breast biopsies performed either in the sitting or prone position were equally well tolerated. Of these patients, 92–96 per cent would undergo such an examination again; this is comparable to the reported 3 per cent of patients who think that diagnostic mammography is an intolerable procedure[18]. However, 22 patients stated they would want anxiolytic premedication if they had to undergo a repeat biopsy. This subgroup of patients did not differ significantly in level of anxiety, pain and motor unrest compared with the rest of the study population. Significantly more patients biopsied in the prone position stated that they would like to be premedicated before a repeat examination. Although the reason for this difference in patient tolerance is speculative, it might be explained by the body position. The fact that patients biopsied in the prone position cannot see what is going on might lead to a feeling of helplessness during the procedure. Fear of losing control during a medical examination is well known[24,25]. Anxiolytic premedication increases tolerance and improves results of MRI[26]. In addition to anxiolytic premedication, alternative interventions should be considered to improve patient tolerance to breast biopsy such as providing improved information about the procedure, and using breathing

Table 3 Vasovagal reactions reported in different interventional breast biopsy procedures

Reference	Year	No. of patients	Vasovagal reactions	Body position	Technique
Goldberg *et al.*[23]	1983	47	1 (2)	Sitting	Wire localization
Parker *et al.*[5]	1990	30	2 (7)	Sitting	Core biopsy (14 G)
		73	0 (0)	Prone	Core biopsy (14 G)
Helvie *et al.*[9]	1991	370	27 (7)	Sitting, prone	Wire localization ($n = 203$), FNAB ($n = 167$)
Reynolds *et al.*[21]	1993	89	1 (1)	Sitting	Wire localization
Caines *et al*[8]	1994	254	4 (2)	Sitting	Core biopsy (16 G, 18 G)
Present results	1996	52	2 (4)	Sitting	FNAB
		51	1 (2)	Prone	FNAB

Values in parentheses are percentages. FNAB, fine-needle aspiration biopsy relaxation techniques before the examination or playing music during the investigation[19,27–30].

Patient tolerance in breast biopsy procedures with regard to anxiety before and after the investigation, pain and motor unrest is high. The present results suggest that breast biopsy is equally well tolerated in the prone and sitting position. However, patient care with regard to information given before the procedure and control of anxiety is important.

Short note

Management of premenopausal women with primary breast cancer

C. B. J. WOODMAN, J. SINGLETON,
J. COYNE* and A. BAILDAM†

In 1992, the report by the Early Breast Cancer Trialists' Collaborative Group on the systemic treatment of early breast cancer by hormonal, cytotoxic and immune therapy suggested that the use of chemoendocrine adjuvant therapy could result in a 30–40 per cent proportional reduction in mortality rate for middle-aged women with primary operable breast cancer[1]. The present paper is the first population-based survey of the management of breast cancer in premenopausal women since the 1992 publication.

Patients and methods

All women aged 50 years or less with primary breast cancer diagnosed between 1 January 1993 and 31 June 1993 were identified from records held by the North Western Regional Cancer Registry. Clinicopathological and therapeutic details were obtained from casenote review. Women were considered to have had adjuvant chemoendocrine therapy if treated with tamoxifen, polychemotherapy (cyclophosphamide/methotrexate and 5-fluorouracil or adriamycin) or had an induced menopause within 3 months of the primary surgical procedure. Axillary sampling was considered inadequate when histological examination of axillary tissue revealed either the presence of axillary fat alone or fewer than four benign axillary lymph nodes. Any positive lymph node was regarded as adequate staging, but at least four negative nodes were required for the patient to be considered node-negative[2]. During the study, hospitals that treated fewer than ten women with invasive cancer in this age group were arbitrarily considered as low-throughput units and those treating ten or more as high-throughput units.

Results

Some 257 women aged 50 years or less with a primary diagnosis of breast cancer were identified. Patients excluded from subsequent analyses included 33 who were peri- or postmenopausal, four with inoperable, locally advanced disease, four with distant metastases and 15 with *in situ* disease alone. Casenotes of four patients were untraceable. Mean age of the remaining 197 patients was 41 (range 24–49) years. Details of primary surgery, tumour histology, axillary node status and use of chemoendocrine therapy are shown in *Table 1*. Primary surgery was undertaken in 26 hospitals. The median number of patients treated in each unit was 12 (range 1–22); 66 women (33·5 per cent) with invasive disease were treated in low-throughput units and 131 (66·5 per cent) in high-throughput units.

Table 1 Primary surgery, tumour histology, axillary lymph node status and use of chemoendocrine therapy

Nodes-negative	88 (44·7)
Mean (range) no. of nodes sampled	8 (4–22)
Inadequate sampling	12 (6·1)
Sampling not attempted	23 (11·7)
Use of adjuvant chemoendocrine therapy ($n = 192$)§	
No adjuvant therapy	46 (23·9)
Tamoxifen alone	64 (33·3)
Chemotherapy and/or tamoxifen	72 (37·6)
Ovarian suppression and/or tamoxifen and/or chemotherapy	10 (5·2)

Values in parentheses are percentages unless otherwise stated. *Women with invasive disease; †those with multifocal disease (two), indiscrete lesion (two) and fragmented specimen (two); ‡those with only infiltrating ductal carcinoma; §exclusions (three refused chemotherapy and two received neoadjuvant therapy)

Fifty-one (77 per cent) and 111 (84·7 per cent) women with invasive disease managed in low- and high-throughput units respectively, had adequate axillary sampling; this difference was not significant ($\chi^2 = 1{\cdot}67$; 1 d.f., $P > 0{\cdot}05$). However, only nine women with positive axillary nodes managed in a low-throughput unit received adjuvant chemotherapy, compared with 53 with positive axillary nodes managed in high-throughput units ($\chi^2 = 11{\cdot}4$; 1 d.f., $P < 0{\cdot}001$). Tumour grade and size were recorded in 42 (81 per cent) and 99 (93 per cent) women with evaluable infiltrating ductal carcinoma (IDC) managed in low- and high-throughput units respectively ($\chi^2 = 5{\cdot}8$; 1 d.f., $P < 0{\cdot}05$). Only nine women who were

Paper accepted 26 December 1995

node-negative with a grade III IDC lesion and none with a tumour more than 3 cm in size received adjuvant therapy. Node-negative women who received chemotherapy were younger (median age 35 years) than those who did not (median age 45 years).

Discussion

The appropriate treatment of primary breast cancer requires identification of women at high risk of metastatic disease[3,4]. Some 82·2 per cent of women in this series had adequate axillary node sampling but the risk status of 17·8 per cent could not be defined because of failure to sample axillary lymph nodes or to describe the size and grade of the primary tumour. It is impossible to opine on the subsequent treatment of these women.

A casenote review cannot always determine when comorbidity or patient preference has caused a deviation from best practice guidelines, but it is disturbing that 12 (16 per cent) women with positive axillary lymph nodes did not receive adjuvant chemotherapy. The optimal management of node-negative disease is less certain, but recent recommendations suggest that some patients with grade III disease or tumours more than 3 cm in size might benefit from adjuvant therapy[5].

The differences between low- and high-throughput units were related not to the willingness of surgeons to sample the axilla, but to the adequacy of pathological reporting and the delivery of adjuvant chemotherapy to high-risk women. Resetting the arbitrary throughput cut-off at a higher level accentuated differences between low- and high-throughput units.

The adoption of good practice guidelines offers the best prospect for improving survival from breast cancer. Progress towards this objective can be measured only by population-based surveys that reflect the totality of clinical management in a defined population.

The findings of this survey suggest that the recommendations of the Early Breast Cancer Trialists' Collaborative Group have not yet been uniformly adopted.

Short note

Altered lymphatic drainage after lymphadenectomy or radiotherapy of the axilla in patients with breast cancer

The incidental occurrence of lymph node metastasis in the contralateral axilla after previous treatment of breast cancer raises the question of whether these metastases derive from the original ipsilateral cancer or from a clinically occult contralateral cancer.

A lymphoscintigraphic study was performed to investigate regional lymphatic drainage patterns of the breast and chest wall before and after axillary dissection or radiotherapy.

Patients and methods

Twenty-three patients with operable breast cancer underwent regional lymphoscintigraphy before treatment. Two patients had clinically suspected ipsilateral involved lymph nodes; none had suspected contralateral nodes. Scintigrams of the chest and axillary regions were obtained 1 and 4 h after subcutaneous administration of 37 MBq (1 mCi) ^{99m}Tc-microcolloid in the medial part of the affected breast, using a large field of view γ camera with a low-energy high-resolution collimator, acquiring counts over 5 min.

The locoregional treatment of the 23 patients consisted of a modified radical mastectomy including axillary dissection (13 patients), breast-conserving treatment including an axillary dissection (eight), wide excision and irradiation of the axilla (one) and irradiation of the breast and axilla (one).

About 6 months after initial treatment, lymphoscintigraphy was repeated in all patients. The radionuclide was again injected in the medial part of the breast or, after mastectomy, cranial to the scar in the mid-clavicular line. Patients were entered in this study only if no clinical signs of recurrence were present at the time of the second scintigram.

Results

Lymphoscintigraphy before treatment

In three of the 23 patients no uptake of radioactivity was seen. In the remaining 20 patients uptake was observed in the ipsilateral nodes (axilla, 19; internal mammary chain, six). Only one patient revealed drainage to the contralateral axilla (*Table 1*).

Lymphoscintigraphy after treatment

In 12 patients no lymph node uptake was seen. In the remaining 11 patients activity was detected in the ipsilateral nodes, in the axilla in two and internal mammary chain in eight. Crossing over to the contralateral nodes was observed seven times in six patients (axilla, six; internal mammary chain, one) (*Table 1*), including the patient who showed contralateral drainage before surgery. Crossing over to the contralateral axilla developed after axillary dissection (four patients) or irradiation of the axilla (one).

Table 1 Regional lymphoscintigraphy before and after treatment in 23 patients with primary breast cancer

	Ipsilateral		Contralateral	
	Axilla	Internal mammary chain	Internal mammary chain	Axilla
Before treatment	19	6	0	1
After treatment	2	8	1	6

In some patients the scintigram showed uptake at more than one station

Discussion

Contralateral lymphatic drainage from the breast occurs occasionally[1,2]. If the normal routes of drainage are blocked by metastases retrograde lymphatic spread to the opposite axilla may occur[3]. However, the one patient in the present study with preoperative contralateral drainage had no axillary lymph node metastases.

The phenomenon of altered lymphatic drainage and crossing over following lymphadenectomy has been reported in melanoma of the lower limb[4]. Lymphatic drainage to the opposite axilla in patients after mastectomy has been shown before, but this was a selected group of patients with lymphoedema of the arm[5]. The present study confirms this observation, although none of the patients had oedema at the time of scanning.

The present observation of altered lymph flow and crossing over offers an explanation of why contralateral axillary metastasis may occur. Because of the altered lymphatic pathways, these nodes should be regarded as having become part of the regional nodes. Particularly in patients with local recurrence of breast cancer, treatment of the contralateral axillary metastasis together with the local recurrence should be considered.

Case report

Duplicated vermiform appendix

K. T. KJOSSEV and J. E. LOSANOFF

Department of Emergency Surgery, Military Medical Academy, Sofia, Bulgaria

Correspondence to. Mr J E. Losanoff, PO Box 159, 1606 Sofia, Bulgaria

Duplicated vermiform appendix is rare: only about 60 cases have been described in the literature[1]. A unique case with atypical localization of the second appendix at the splenic flexure is reported.

Case report

A 32-year-old man presented with continuous left upper abdominal pain of 11-h duration. He was nauseated but had not vomited and had had a normal bowel movement the night before admission. Body temperature was 37·9°C, pulse 96 beats per min, respiratory rate 28 per min and blood pressure 150/90 mmHg. Examination was unremarkable except for tenderness in the left upper abdominal quadrant. Laboratory values were all within normal limits except for a leucocytosis of $14 \cdot 6 \times 10^9$ cells/l. Chest and abdominal plain films and abdominal ultrasonography were normal.

Following admission the patient remained stable but febrile. The pain increased, the abdomen became more tender and the white blood cell count increased to $18 \cdot 1 \times 10^9$/l. Midline laparotomy was performed, and a gangrenous vermiform appendix was found arising from the antimesenteric aspect of the left colic (splenic) flexure; it was approximately 8 cm long. The mesoappendix arose from the mesocolon inferiorly. Appendicectomy was performed in the usual manner. No other intra-abdominal pathology was observed, but a normal vermiform appendix was found in a typical anatomical position and a second appendicectomy was performed. The abdomen was drained. After an uneventful recovery the patient was discharged 7 days later.

Discussion

Duplication of the vermiform appendix is extremely rare; it is found in only 0·004 per cent of patients operated on for acute appendicitis[2]. In the authors' department this has been the only case of vermiform appendix duplication among 10 956 appendicectomies performed between 1965 and 1995, representing 0·009 per cent of all appendicectomies.

According to the classification of Cave[3], modified by Wallbridge[4], there are three main types of duplication: A, B (subdivided into B1 and B2) and C; in 1993 Biermann *et al.*[2] proposed an additional subtype, B3 (*Fig. 1*). To the best of the authors' knowledge, a second vermiform appendix arising from the splenic flexure has not been described previously. This localization may be classified as a B4 subtype.

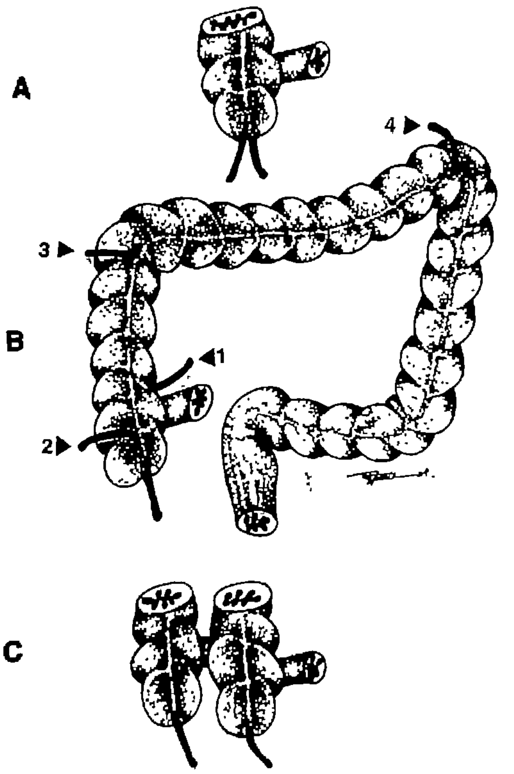

Fig. 1 Schematic drawing illustrating the classification of all known types of vermiform appendix duplication according to Cave[3], Wallbridge[4], Biermann *et al.*[2] and the authors' own observation. Type A, incomplete duplication with both appendices having a common base; type B, complete duplication with the first appendix arising from the caecum where all three taeniae join and the second appendix arising as follows: contralaterally from the caecum (B1), more distally from the ascending colon (B2), from the hepatic flexure (B3) and from the splenic flexure (B4); type C, complete duplication of the caecum, each caecum having its own appendix

Prospective comparison of laparoscopy, ultrasonography and computed tomography in the staging of gastric cancer

D. A. STELL, C. R. CARTER, I. STEWART* and J. R. ANDERSON

*University Department of Surgery and *Department of Radiology, Royal Infirmary, Glasgow, UK*
Correspondence to: Mr J R. Anderson, Southern General Hospital, 1345 Govan Road, Glasgow G51 4TF, UK

A total of 103 consecutive patients with gastric adenocarcinoma was assessed for intra-abdominal spread of malignancy using ultrasonography, computed tomography (CT) and laparoscopy under general anaesthesia. Histologically proven metastases were to the liver in 27 patients, lymph nodes in 49 and directly to peritoneum in 13. All modalities showed a high specificity (92–100 per cent) for each type of metastasis. Laparoscopy was more sensitive in detecting hepatic, nodal and peritoneal metastases; the relative performance of laparoscopy was best with regard to hepatic metastases. Ultrasonography and CT were particularly poor at detecting nodal and peritoneal metastases. There was no significant morbidity and no mortality associated with laparoscopy, which was more accurate in preoperative staging of gastric cancer than ultrasonography or CT.

Despite a declining incidence, gastric cancer remains the fourth most common malignant tumour in the UK, causing 11 000 deaths per year[1]. Preoperative staging for spread of the disease is routinely performed in most centres using ultrasonography and computed tomography (CT). Staging of gastric cancer guides the clinician regarding prognosis, assists in operative planning and may prevent unnecessary laparotomy in selected patients for whom non-operative therapies are now available. CT and ultrasonography both have limitations in staging gastric cancer. CT achieves accuracy rates of 29–72 per cent for the detection of hepatic metastases in recently reported series[2–7], with most authors agreeing that it is not reliable for staging the disease without other investigations. Laparoscopy is of proven benefit in the staging of oesophageal cancer[8]. The aim of this study was to compare the accuracy of ultrasonography, CT and laparoscopy in the staging of patients with gastric adenocarcinoma.

Patients and methods

Between 1988 and 1991, 103 consecutive patients with biopsy-proven gastric adenocarcinoma were assessed. All carcinomas were included except tumours localized to the cardia, which have previously been studied[8]. Patients with gastric lymphoma were excluded. Ultrasonography was performed using an Advanced Technology Laboratories (Washington, UK) real-time ultrasound scanner fitted with a 3.5-MHz transducer and contrast-enhanced CT using a GE model 9800 Hilight whole-body scanner (GEC, Milwaukee, Wisconsin, USA). Laparoscopy was performed under general anaesthesia with intermittent positive-pressure ventilation as a separate staging procedure. An Olympus (Keymed, Southend, UK) 30° oblique viewing laparoscope was used with an Eder Insumat carbon dioxide Insufflator (Down Surgical, Mitcham, UK). The laparoscope was usually inserted subumbilically, and, when indicated, a liver sample biopsy was obtained using a Tru-Cut (Travenol Laboratories, Deerfield, Illinois, USA) biopsy needle. Intra-abdominal metastases were considered to be proven only when histological confirmation was available Nodal and peritoneal metastases therefore required laparotomy to obtain material for histological examination. Hepatic metastases were biopsied percutaneously under direct vision. All investigations were carried out by experienced personnel, who were unaware of the results of previous investigations. The sensitivity, specificity and accuracy of each technique were calculated and the results compared using an uncorrected χ^2 test. The sensitivity of an investigation is the proportion of positive tests in all patients with proven disease, the specificity is the proportion of negative tests in all patients proven to be disease-free, and the accuracy is the ratio of correct results (true positive and true negative) to the total number of tests.

Results

There were 68 men and 35 women aged between 33 and 91 years, with a mean age of 65 years. The distribution of tumours is shown in *Table 1*. Of the 103 patients, 22 had biopsy-proven hepatic metastases at laparoscopy and were treated without surgery (four with hepatic metastases at laparoscopy proceeded to laparotomy and one with a negative laparoscopy was found to have hepatic metastases at laparotomy). A further 16 patients were also treated conservatively: ten had obvious peritoneal metastases at laparoscopy, three had advanced nodal disease and were medically unfit, two declined surgery despite being free from metastases at staging and one had pulmonary metastases detected radiologically. These 16 patients are excluded from the study as the findings at staging could not be confirmed surgically. The remaining 65 patients proceeded to laparotomy.

Of the 38 patients treated without surgery, 31 had laser therapy to control local disease, five had pulsion intubation, one had chemotherapy alone and one had no treatment. In this group, there were 11 patients with hepatic metastases and ten with peritoneal metastases, which were detected only by laparoscopy.

Table 1 Distribution of gastric tumours

	No. of tumours
Proximal third of stomach	60
Body of stomach	24
Antrum	10
Body and antrum	6
Fundus	2
Linitis plastica	1

Presented to the Surgical Research Society in Glasgow, UK, July 1994
Paper accepted 10 October 1995

Fifty-three of the 65 patients treated surgically had resection of the primary tumour. Of the remaining 12 patients with unresectable local disease, five had operative intubation, three had laser therapy, two had chemotherapy, one had a palliative gastrojejunostomy, and one had a laparotomy and died before further treatment. All patients undergoing laparotomy had biopsy of peritoneal deposits and sampling from all accessible nodal areas.

Twenty-seven patients had histologically confirmed liver metastases either at laparotomy and biopsy ($n = 1$) or by laparoscopy and percutaneous biopsy ($n = 26$). Forty-nine of the 65 patients undergoing surgery had histologically proven nodal metastases, and 13 had proven peritoneal deposits. Of the 65 patients undergoing surgery, only 16 had the disease confined to the stomach.

Laparoscopy was significantly more sensitive than other modalities in the detection of liver metastases. Of the 27 patients with histologically proven liver metastases, 26 were correctly identified by laparoscopy, compared with ten by ultrasonography and 14 by CT (*Table 2*). The one false negative reported by laparoscopy was in a patient who had two small posterior hepatic metastases, one in the right and one in the left lobe. These lesions were also missed by ultrasonography and CT.

Table 2 Comparison of indices for hepatic metastases in the staging of gastric adenocarcinoma by three modalities*

	Laparoscopy	Ultrasonography	CT
True positive	26	10	14

False positive	0	3	5
False negative	1	17	13
Accuracy (%)	99	76	79

*Hepatic metastases were histologically proven in 27 patients and confirmed absent in 60.
Sensitivity: laparoscopy *versus* ultrasonography $\chi^2 = 21{\cdot}33$, 1 d.f., $P < 0{\cdot}001$; laparoscopy *versus* CT $\chi^2 = 13{\cdot}89$, 1 d.f., $P < 0{\cdot}001$. Specificity: laparoscopy *versus* ultrasonography $\chi^2 = 3{\cdot}08$, 1 d.f., $P < 0{\cdot}1$; laparoscopy *versus* CT $\chi^2 = 5{\cdot}22$, 1 d.f., $P < 0{\cdot}05$. Accuracy: laparoscopy *versus* ultrasonography $\chi^2 = 18{\cdot}43$, 1 d.f., $P < 0{\cdot}001$; laparoscopy *versus* CT $\chi^2 = 16{\cdot}1$, 1 d.f., $P < 0{\cdot}001$. CT, computed tomography

Table 3 Comparison of indices for nodal metastases in the staging of gastric adenocarcinoma by three modalities*

	Laparoscopy	Ultrasonography	CT
True positive	26	6	13
Sensitivity (%)	53	12	27
True negative	16	16	16
Specificity (%)	100	100	100
False positive	0	0	0
False negative	23	43	36
Accuracy (%)	65	34	45

*Nodal metastases were histologically proven in 49 patients and confirmed absent in 16. Sensitivity: laparoscopy *versus* ultrasonography $\chi^2 = 18{\cdot}56$, 1 d.f., $P < 0{\cdot}001$; laparoscopy *versus* CT $\chi^2 = 7{\cdot}19$, 1 d.f., $P < 0{\cdot}01$. Accuracy: laparoscopy *versus* ultrasonography $\chi^2 = 12{\cdot}31$, 1 d.f., $P < 0{\cdot}001$; laparoscopy *versus* CT $\chi^2 = 5{\cdot}24$, 1 d.f., $P < 0{\cdot}05$. CT, computed tomography

Table 4 Comparison of indices for peritoneal metastases in the staging of gastric adenocarcinoma by three modalities*

	Laparoscopy	Ultrasonography	CT
True positive	9	3	1
Sensitivity (%)	69	23	8
True negative	52	52	52
Specificity (%)	100	100	100
False positive	0	0	0
False negative	4	10	12
Accuracy (%)	94	84	81

*Peritoneal metastases were histologically proven in 13 patients and absent at laparotomy in 52. Sensitivity: laparoscopy *versus* ultrasonography $\chi^2 = 5{\cdot}57$, 1 d.f., $P < 0{\cdot}05$; laparoscopy *versus* CT $\chi^2 = 10{\cdot}40$, 1 d.f., $P < 0{\cdot}1$. Accuracy: laparoscopy *versus* ultrasonography $\chi^2 = 2{\cdot}88$, 1 d.f., $P < 0{\cdot}1$; laparoscopy *versus* CT $\chi^2 = 4{\cdot}56$, 1 d.f., $P < 0{\cdot}05$. CT, computed tomography

Of the 27 patients with hepatic metastases, nine were identified by all three modalities, five by laparoscopy and CT alone, one by laparoscopy and ultrasonography alone, and 11 by laparoscopy alone. Laparoscopy did not achieve the same sensitivity with regard to nodal metastases, detecting only 26 of the 49 histologically proven cases compared with six by ultrasonography and 13 by CT (*Table 3*).

Of the 13 patients with histologically proven peritoneal metastases, nine were detected by laparoscopy compared with three by ultrasonography and one by CT (*Table 4*). All three patients correctly identified by ultrasonography had ascites from which the presence of peritoneal metastases was inferred. The four false-negative results reported by laparoscopy included one metastatic deposit in the transverse mesocolon, one deposit on the posterior surface of the greater omentum and one deposit lying on the pancreas. One diaphragmatic peritoneal metastasis was also missed at laparoscopy.

Discussion

The present series of 103 patients shows a majority of proximal third lesions compared with those of the distal third. This may reflect referral bias in the authors' unit which has an interest in the management of dysphagia, but is in keeping with observed recent trends[9]. The value of preoperative staging for these patients lies in identifying those who will not benefit from resectional or bypass surgery. This is becoming of increasing importance with the advent of non-operative means of tumour palliation: chemotherapy, laser therapy and intubation. None of the patients in the study who underwent palliative therapy required surgery before death. Despite these treatment methods, however, some patients with metastases demonstrated by staging will require palliative surgery, particularly those with lesions of the antrum causing gastric outlet obstruction.

The detection of nodal metastases is of lesser importance than hepatic metastases as their presence does not always preclude surgical resection of the tumour; indeed laparoscopy is unlikely to detect small nodal deposits or nodal disease around the coeliac axis. Laparoscopy as used in this series had limitations in the detection of peritoneal metastases as a single viewing port was used without the aid of dissecting or manipulating instruments. For this reason, deposits concealed by the stomach, omentum or mesentery were not accessible. The development of improved laparoscopic techniques now enables dissection and biopsy for histological confirmation to be performed with ease. Ultrasonography and CT are able only to suggest the presence of peritoneal metastases by the detection of ascites, and the difference between the two modalities in the present study probably reflects interobserver variation.

However, all three modalities were highly specific; laparoscopy achieved significantly higher specificity than CT only in the detection of hepatic metastases ($\chi^2 = 5{\cdot}22$, 1 d.f., $P < 0{\cdot}05$). This is reflected in the accuracy rates which are also high for all three modalities, although laparoscopy is significantly more accurate than other modalities except in comparison with that of ultrasonography in the detection of peritoneal metastases.

Another benefit of performing laparoscopy as a separate staging procedure is that it allows an assessment of the patient's ability to tolerate anaesthesia and surgical trauma before embarking on resectional surgery.

The 1987 Union Internacional Contra la Cancrum classification of gastric cancer categorizes tumour spread according to the tumour node metastasis (TNM) system. Laparoscopy is of particular value in assessing metastases distant from the primary tumour site (M stage). It also provides the opportunity to biopsy under vision suspected hepatic metastases, thereby avoiding the ambiguity often associated with radiological investigation. Laparoscopy tends to understage nodal disease, particularly retrogastric involvement, and provides little information about depth of tumour invasion unless the serosa is breached. Endoscopic ultrasonography is proving increasingly accurate at staging T and N disease[10,11]. Laparoscopic ultrasonography may increase the detection of lymphadenopathy; however, as this does not prove the presence of metastatic disease, it is unlikely to reduce the need for laparotomy. In the present study the 'gold standard' for comparing the accuracy of the different modalities is taken as being the findings at laparotomy and tissue sampling. The results show that all modalities underestimate the extent of disease. More recent methods of detecting microscopic or 'occult' metastases such as intraoperative ultrasonography or hepatic perfusion studies have not yet been fully assessed in gastric cancer.

Published work gives conflicting opinions on the value of laparoscopy in staging gastric cancer. In an early work Possik *et al.*[12] evaluated 360 patients and attained a sensitivity of 87·2 per cent for laparoscopy in the detection of hepatic metastases, concluding that it is a superior diagnostic method than radiological tests. Kriplani and Kapur[13] attained an accuracy of 91·6 per cent in the detection of hepatic metastases in a series of 40 patients and Forse and colleagues[14] demonstrated the benefit of laparoscopy in reducing the hospital stay of patients with an unresectable tumour.

Despite this work, laparoscopy has not gained popularity in the staging of gastric cancer. In a large multicentre study published by the German Gastric Cancer TNM Study Group in 1989[15] diagnostic laparoscopy was dismissed as being 'of limited clinical utility' in the staging of gastric cancer. Some 37 per cent of the present series did not undergo surgery as a result of findings at staging and laparoscopy had the major role in identifying this group.

Laparoscopy offers a safe, sensitive and specific method of staging patients with gastric carcinoma. This is of increasing importance in planning patient management with the use of non-operative methods of tumour palliation.

Pharyngo-oesophageal function was investigated in 12 patients with Zenker's diverticulum before and after cricopharyngeal myotomy with or without diverticulectomy using low-compliance, high-frequency oesophageal manometry. Nine healthy volunteers served as controls. The amount of muscle and connective tissue in the cricopharyngeal muscle was also measured by computerized morphometry and compared with findings in cadavers with no history of dysphagia. Preoperative manometry in patients with Zenker's diverticulum showed an incomplete relaxation of the upper oesophageal sphincter (UOS) (the residual UOS pressure at swallowing was 7·9 (range 1–20) mmHg in patients *versus* 0·2 (−12·5–14) mmHg in controls; $P<0·001$) and increased pharyngeal intrabolus pressure (21 (range 0–52) *versus* 9 (range 0–16) mmHg; $P<0·01$), with no pharyngo-oesophageal coordination abnormalities. Both parameters significantly decreased after myotomy. Patients with Zenker's diverticulum had significantly fewer muscle fibres in the cricopharyngeus and the muscle:connective tissue ratio was significantly lower (0·94 (range 0·8–1·4) in patients *versus* 1·5 (1·4–3·6) in controls; $P<0·05$). This study supports the theory that Zenker's diverticulum is caused by an increased intrapharyngeal pressure at swallowing due to incomplete cricopharyngeal muscle relaxation resulting from localized sclerosis.

The role of disordered cricopharyngeal muscle function in the pathogenesis of pharyngeal pouches – or so-called Zenker's diverticula – remains unclear. There is equally no agreement as to the role of cricopharyngeal myotomy in their treatment. This study was therefore undertaken to study cricopharyngeal muscle function (as evaluated by manometry) and morphology in a group of 12 consecutive patients with Zenker's diverticulum, and to evaluate changes induced by myotomy and diverticulectomy in pharyngo-oesophageal function.

Patients and methods

Between January 1991 and May 1995, 12 patients (four women and eight men of median age 65 (range 43–79) years) were referred with symptoms related to Zenker's diverticulum. They all complained of dysphagia, described as a sense of food sticking in the throat, and this was defined as severe (interfering with normal activity) in five and moderate in seven. Regurgitation of food was reported in ten and aspiration (nocturnal coughing, wheezing and/or recurrent pneumonia) occurred in seven. Dysphagia and regurgitation were scored according to intensity (1 = mild, not reported spontaneously by the patient; 2 = moderate, reported spontaneously but not interfering with normal activity; and 3 = interfering with normal activity) and frequency (1 = occasionally; 2 = once a week; 3 = twice or three times a week; and 4 = daily). Aspiration symptoms were scored as present (1) or absent (0). The sum of the scores for the single symptoms was considered as the patient's symptom score. The median duration of symptoms was 12 (range 2–48) months

The diagnosis of Zenker's diverticulum was usually obtained with a barium swallow. The diverticula measured (in their longest axis) less than 2 cm in three patients, between 2 and 4 cm in seven and more than 4 cm in two. All patients underwent oesophageal manometry and upper gastrointestinal endoscopy to exclude any concomitant abnormalities of the oesophagus and stomach. In the event of the diverticulum interfering with its placement, the manometric probe was passed with the aid of a guidewire positioned at endoscopy.

Nine healthy volunteers (seven men and two women of median age 38 (range 24–80) years) served as a control group.

Manometric evaluation

Manometry was performed with the instruments and technique described in detail elsewhere[1]. Briefly, an eight-lumen low-compliance infused system with computerized data acquisition and analysis was employed. A high-frequency data acquisition mode (50 Hz) was used in view of the rapidity of events occurring during swallowing. Upper oesophageal sphincter (UOS) pressure was measured while the catheter was withdrawn at a constant rate of 5 mm/s. The maximum amplitude registered by each probe during its passage through the UOS was averaged and considered as the UOS pressure. To evaluate the pharyngo-oesophageal segment, the manometric probe with four radially orientated side holes was positioned at the upper edge of the UOS, with two other side holes situated 5 and 10 cm above (in the distal and proximal pharynx respectively) and one 5 cm below (in the cervical oesophagus). Five swallows of 5 ml water were evaluated. The following parameters of pharyngeal contractions were considered: amplitude, duration and intrabolus pressure, i.e. the pressure generated by the passage of the bolus in the distal pharynx and seen at manometry as a slow pressure increase (shoulder) before the major upstroke generated by contractions of the pharyngeal wall, as described by Cook *et al.*[2] (*Fig. 1*), UOS relaxation (expressed as the residual pressure at swallowing) and the coordination of UOS opening with pharyngeal contractions, as described by Knuff *et al.*[3].

Operation

A left laterocervical approach, anteromedial to the sternocleidomastoid muscle, was used. All the diverticula were excised and, if 2 cm or greater in size, transected with a stapler. Small diverticula were left in place in three patients. The cricopharyngeal muscle fibres were divided in the midline

Paper accepted 20 November 1995

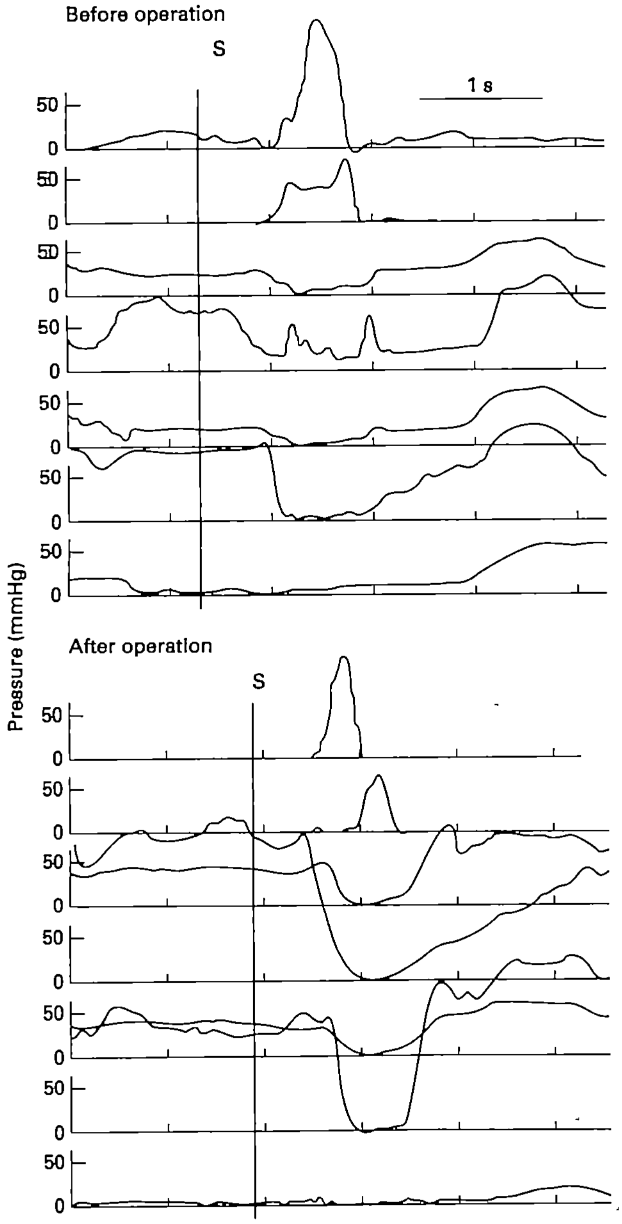

Fig. 1 Pharyngo-oesophageal manometry in a patient with Zenker's diverticulum before (above) and after (below) diverticulectomy and myotomy. The manometric probes are positioned in the proximal pharynx (upper trace), in the distal pharynx (second trace), at the upper edge of the upper oesophageal sphincter (UOS), 90° apart (the four central traces) and in the proximal oesophagus (lower trace) 5 cm below the upper edge of the UOS. The fourth probe is directed towards the right lateral wall of the UOS and an incomplete relaxation of the UOS is detected only by this probe, probably because of the UOS asymmetry. The sensor immediately above (in the distal pharynx) records a slow increase in pressure (intrabolus pressure) immediately before the major upstroke, indicating a slow passage of the bolus through the sphincter because of reduced compliance or incomplete relaxation. Both findings are no longer evident after surgery. The vertical lines (S) mark the swallows

posteriorly from the neck of the sac down to the oesophagus for 4–5 cm. Specimens of cricopharyngeal muscle were collected in seven patients. A Nissen fundoplication was also performed in one patient with gastro-oesophageal reflux and hiatus hernia.

Histological and morphometric studies

The muscle biopsy specimens were fixed in 10 per cent buffered formalin. Morphometry was performed on Masson's trichrome-stained sections, using a computerized image analysis system (AT-IBAS, Kontron, Eching, Germany), connected through a black and white television camera (Bosch TYK9B) to an optical microscope (UMSP80, Zeiss, Oberkochen, Germany). Sections were sampled field by field and two images for each field were stored using a monochromatic light of 400 and 450 nm respectively. After correction for uneven illumination and contrast enhancement, the areas occupied by connective tissue or muscle fibres were distinguished by means of a suitable threshold and the area fractions were measured. The grey threshold was maintained constant for the whole measurement. Three sections for each sample were examined and the values obtained were averaged.

Five specimens of cricopharyngeal muscle collected from sex- and age-matched cadavers with no history of dysphagia or presence of diverticulum at post-mortem examination served as a control group.

Statistical analysis

Findings were stored in a database (DB3, Ashton Tate, USA) and analysed using a commercially available statistical package (Statgraphics, STSC Plus Ware Product, USA). The Wilcoxon and Mann–Whitney *U* tests were used, as appropriate. Values are expressed as median (range).

Results

Surgical outcome

One patient had a leak which was treated conservatively, maintaining the patient on enteral nutrition via nasogastric tube for 10 days. The median follow-up was 5 (range 3–35) months and all but two patients were asymptomatic; two complained of occasional moderate dysphagia. The symptom scores before and after surgery are shown in *Fig. 2*.

Manometric findings

Patients with Zenker's diverticulum had increased intrabolus pressure in pharyngeal contractions and an increased residual UOS pressure at swallowing (*Fig. 3*). Their resting UOS pressure was lower, though not significantly so, than in controls. No differences were observed in pharyngo-oesophageal coordination, duration of UOS opening, or amplitude and duration of pharyngeal contractions (*Table 1*).

A statistically significant reduction in intrabolus pressure, minimal UOS pressure at swallowing and resting UOS pressure was observed in the nine patients who agreed to undergo a repeat manometric test a median of 3 (range 1–35) months after operation (*Fig. 4*).

Histological and morphometric studies

Histological examination of the seven specimens showed a marked decrease in the amount of muscle fibre in the cricopharyngeus. The muscle:connective tissue ratio was consequently significantly lower in patients than in controls (*Fig. 5*).

Discussion

Since the first case of pharyngo-oesophageal pouch was described by Ludlow in 1764[4], many theories have been

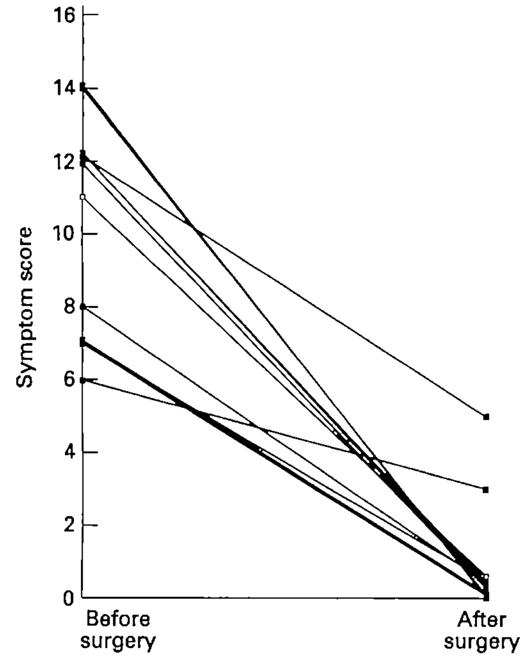

Fig. 2 Symptom scores for each patient before and after surgery. Two patients still had moderate dysphagia after treatment

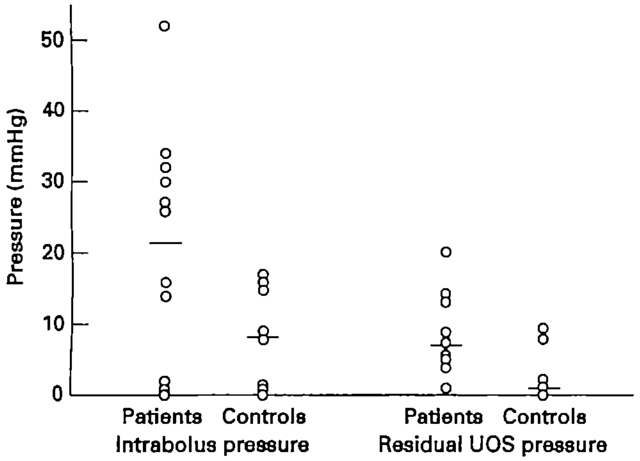

Fig. 3 Intrabolus pressures (left) and residual upper oesophageal sphincter (UOS) pressures at swallowing (right) in patients and controls. Both measurements differ significantly ($P<0{\cdot}01$ and 0·001 respectively, Mann-Whitney *U* test)

Table 1 Pharyngosphincteral manometric parameters in patients with Zenker's diverticulum

	Patients	Controls
Pharyngeal contractions		
Amplitude (mmHg)	68·0 (27–105)	34·5 (10·3–62)
Duration (s)	0·7 (0·5–1·0)	0·9 (0·1–1·0)
UOS		
Resting pressure (mmHg)	35·0 (24–60)	57·8 (25·7–90)
Duration of relaxation (s)	1·3 (0·8–1·9)	1·0 (0·8–1·3)
Time difference between pharyngeal peak and maximum UOS relaxation (s)	0·2 (0·6–0·1)	0·3 (1·1–0·1)

Values are median (range). UOS, upper oesophageal sphincter

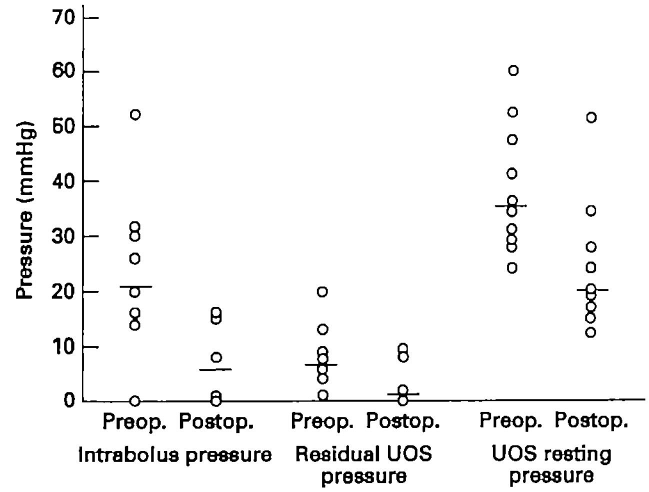

Fig. 4 Preoperative and postoperative manometric readings of the pharynx and oesophagus in nine patients with Zenker's diverticulum. The intrabolus pressure decreased from 21 to 8 mmHg; the residual upper oesophageal sphincter (UOS) pressure at swallowing decreased from 7·9 to 1·8 mmHg; and the UOS resting pressure decreased from 35 to 20 mmHg. All three measurements were statistically significant ($P<0{\cdot}05$, Wilcoxon test)

postulated to explain its aetiology. Zenker and Von Ziemssen[5] proposed that herniation of the pouch proximal to the cricopharyngeal muscle might be caused by high pharyngeal pressures, the actual site of herniation being determined by a zone of weakness in the posterior wall – the so-called Killian's dehiscence. The suggestion that the cricopharyngeal muscle might be involved in the development of Zenker's diverticulum arose initially from endoscopic and radiographic studies describing premature contractions of the cricopharyngeus and failure to achieve relaxation (achalasia of the UOS)[6,7]. When pharyngo-oesophageal function was investigated by manometry, however, the findings were inconsistent. In the early 1980s, attention focused on delayed UOS opening in relation to pharyngeal contraction and a lack of UOS coordination became the most widely accepted assumed cause of Zenker's diverticulum[8,9]. Manometric tests failed to detect any abnormality in 40–60 per cent of patients with Zenker's diverticulum, however, and this theory was further undermined by subsequent research: Knuff, for example, observed no manometric abnormality in nine patients with Zenker's diverticulum.

There are several reasons why manometric testing may fail to detect pharyngo-oesophageal function abnormalities in Zenker's diverticulum: the cricopharyngeal muscle, which roughly corresponds to the UOS, generates asymmetric pressures with a considerable variability in each of the axes[10]; contractions of the pharyngeal striated muscle cause pressure events to be much faster and greater in amplitude than in the distal oesophagus[11]; moreover, the UOS is extremely mobile and moves proximally nearly 1 cm during swallowing, thus causing the recording site to 'drop out' if it is placed in the central part of the UOS. This 'dropping out' of the recording site may explain the apparently 'normal' relaxation observed by previous researchers.

Manometric study of the pharyngo-oesophageal complex calls for a careful method and suitable technology: to

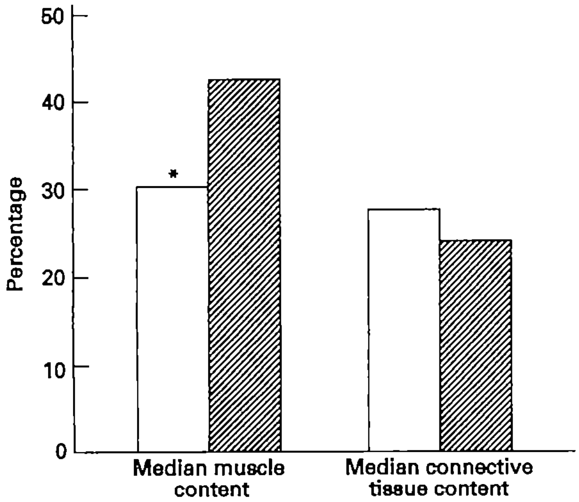

Fig. 5 Median content of muscle (left) and connective tissue (right) in the cricopharyngeal muscle of patients with Zenker's diverticulum (□) and cadaveric specimens of subjects without dysphagia (▨). Muscle: 30·1 per cent in patients *versus* 42·6 per cent in controls ($^*P < 0·05$, Mann-Whitney U test); connective tissue: 27·4 per cent in patients *versus* 23·9 per cent in controls

overcome the asymmetry, four side holes at the same level were used in the UOS; higher frequency sampling was used to detect the faster events in the pharynx and the four side holes were carefully positioned at the upper margin of the UOS to avoid any 'drop-out' phenomena. Although optimal recording of pharyngeal contractions can be achieved only by solid-state catheter, the present study was not intended to measure maximum intrapharyngeal pressures. The perfused side holes certainly underestimate the maximum pressure, but they none the less detect intrabolus pressures with a low rate of increase, which were measured well within the capability of the system. The authors' method was very similar to the one described by Cook *et al.*[2] (except for sleeve probes into the UOS rather than side holes) and very similar results were obtained. The main abnormality detected in patients with Zenker's diverticulum was a failure to achieve complete relaxation and a consequent increase in pharyngeal intrabolus pressure during the phase of trans-sphincter bolus flow. This manometric finding is probably related to a primary cricopharyngeal muscle dysfunction. In fact, the finding of a normal duration and coordination of UOS opening suggests that the disorder is caused by a diminished sphincter compliance rather than by pharyngeal incoordination. The observation by Cook and colleagues[2] that hyoid motion is normal in extent and timing in patients with Zenker's diverticulum also supports a localized mechanical disturbance rather than a lack of neuromuscular coordination.

Cricopharyngeal muscle alterations have been reported: Lerut *et al.*[12] observed a weaker contraction curve with a lower amplitude, a longer time to peak twitch and a much longer muscle fibre relaxation time in an '*in vitro* study' on patients with Zenker's diverticulum. The muscle fibres also showed a reduction in their content of acetylcholinesterase, a predominant distribution of type I muscle fibres and an increase in fibrotic tissue. The results of the present study confirm and objectively measure the reduction in muscle fibres in the cricopharyngeal muscle. This probably causes the reduced compliance and contractility of the muscle. The aetiology of this relative fibrosis is not known. Lerut and co-workers[12] took biopsy samples from the sternocleidomastoid muscle of patients with Zenker's diverticulum and found no abnormalities, thus excluding the presence of any generalized myopathy. Whether these morphological and functional changes are primary causal factors in the genesis of Zenker's diverticulum, or merely secondary to the compression caused by the diverticulum itself, remains to be seen. However, the reduction in muscle component was found in smaller Zenker's diverticula as well as in larger ones, and it is hardly likely that a 2-cm pouch could cause sufficient compression on the cricopharyngeal muscle to give rise to such changes.

Cricopharyngeal myotomy in association with diverticulectomy or diverticulopexy has gained in popularity in the past 20 years and has been widely used, despite the lack of manometric evidence of any cricopharyngeal muscle function impairment in Zenker's diverticulum[13]. The reason for adding a myotomy was mainly based on the observation of a lower complication rate when myotomy was added, as reported in a survey carried out in the Group Européen d'Etude des Maladies de l'Oesophage[14]. This strictly empirical experience seems to confirm the role of the cricopharyngeal muscle in symptoms of Zenker's diverticulum, justifying myotomy as an essential step in its treatment.

The effect of myotomy was evident in the present patients, with a decrease in UOS resting pressure and residual UOS pressure at swallowing, and a reduction in pharyngeal intrabolus pressure. The relief from dysphagia (which cannot be explained by the diverticulectomy alone, as an improvement in symptoms was also obtained in patients with small diverticula left untouched) is probably related to the improved relaxation of the UOS due to the myotomy. This being so, a much higher incidence of recurrence would be expected if myotomy was not performed – but this is not the case, possibly because recurrence might take a long time to develop and, as patients with Zenker's diverticulum are elderly, most will die before any recurrence becomes apparent.

In conclusion, this study confirms the old Zenker and Von Ziemssen[5] hypothesis of an increased intrapharyngeal pressure in the pathogenesis of pharyngeal pouches and of the central role played by the cricopharyngeal muscle. The reduction in cricopharyngeal muscle compliance is probably related to the reduction in muscle fibres and qualitative alterations of the fibres. Cricopharyngeal myotomy is therefore an essential part of the treatment of Zenker's diverticulum.

Anatomy of the extrinsic motor nerve supply to mobilized segments of the oesophagus disrupted by dissection during repair of oesophageal atresia with distal fistula

M. R. Q. DAVIES

Division of Paediatric Surgery, University of the Witwatersrand Medical School, Johannesburg, South Africa
Correspondence to: Professor M. R. Q. Davies, Division of Paediatric Surgery, 154/28 Johannesburg Hospital, Private Bag X39, Johannesburg 2000, South Africa

Atresia of the oesophagus occurs near to the site of convergence of the foregut with structures of branchial arch origin. This is a confluence of a striated muscle tube with a somatic nerve supply and a smooth muscle tube with an autonomic nerve supply. The implications, with regard to function, of denervating the oesophagus during operation are influenced by this anatomy. During dissection of a cadaver with oesophageal atresia and distal fistula, the sites of potential nerve injury were displayed. Damage to these nerves occurs during routine primary repair and may contribute to oesophageal motor dysfunction after successful surgery.

Patients who have had an oesophageal atresia with distal fistula repaired seldom complain about their ability to swallow even though they have significant functional abnormality which can be confirmed by manometric evaluation[1,2]. Never having experienced normal function, symptoms that would be incapacitating for many remain unrecognized.

The anatomy of the vagus nerve, the extrinsic motor supply to the oesophagus and stomach, has surgical importance and little attention has been given to the branches that supply the pharynx and oesophagus. The possibility of disruption of this supply during repair of an oesophageal atresia has not been addressed previously, although nerve damage to the mobilized segments is known to occur[3–5].

A cadaveric dissection performed to illustrate the site of nerve disruption during primary repair of an oesophageal atresia of the common type is described.

Methods

The extrinsic motor nerve supply to the proximal and distal segments of an unrepaired oesophageal atresia with distal tracheo-oesophageal fistula was identified by dissection. The oesophageal pouch and fistula segments were mobilized surgically, and nerve damage was noted and photographed (*Figs 1–3*). Attention is drawn to the fact that the recurrent nerves and their branches were dissected and released from surrounding tethering structures in the illustrations. This allowed the nerves to be identified clearly.

Results

An extensive plexus of nerves surrounds the oesophagus immediately distal to the tracheo-oesophageal fistula. The right vagus and its branches form its proximal part but it is soon joined by major contributions from the left vagus nerve.

The proximal portion of the oesophagus distal to the tracheo-oesophageal fistula could easily be mobilized within this plexus, but small direct branches to the oesophagus were divided during dissection.

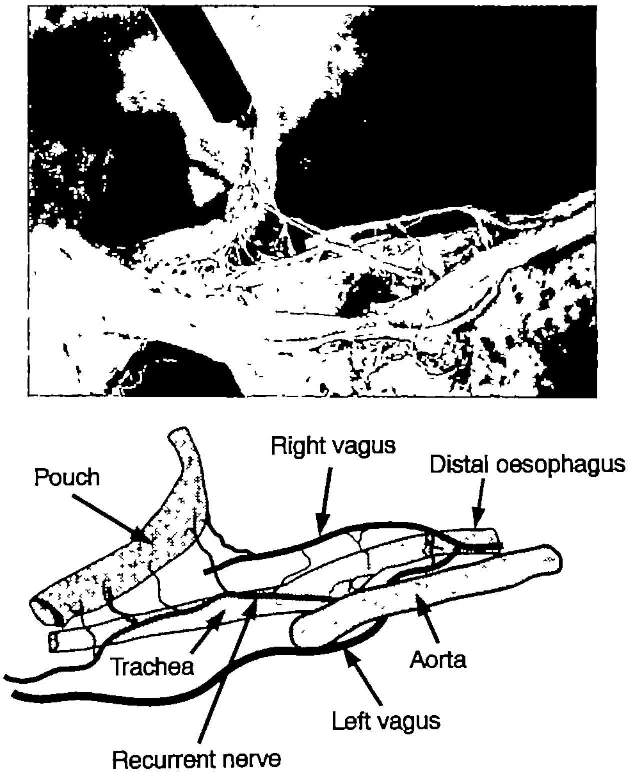

Fig. 1 Left vagus and left recurrent laryngeal nerve. The specimen is in the prone position, with the craniad end to the left. The tip of the atretic oesophagus has been transfixed by a probe. The distal part of this structure was dissected free from all tethering fibres and nerves. Uncut nerves to the pouch are shown. Note the segmental nature of this supply. The right vagus and its branches have been lifted off the proximal end of the distal oesophagus. The left recurrent laryngeal nerve arises from the vagus as this nerve passes in front of the aorta

In the presence of oesophageal discontinuity, a plexus of nerves lies on the trachea immediately distal to the atresia. These nerves have their origin from the right vagus and left recurrent laryngeal nerves. This plexus was damaged during dissection of the proximal pouch. As this structure was lifted off and mobilized from the trachea, its

Paper accepted 10 December 1995

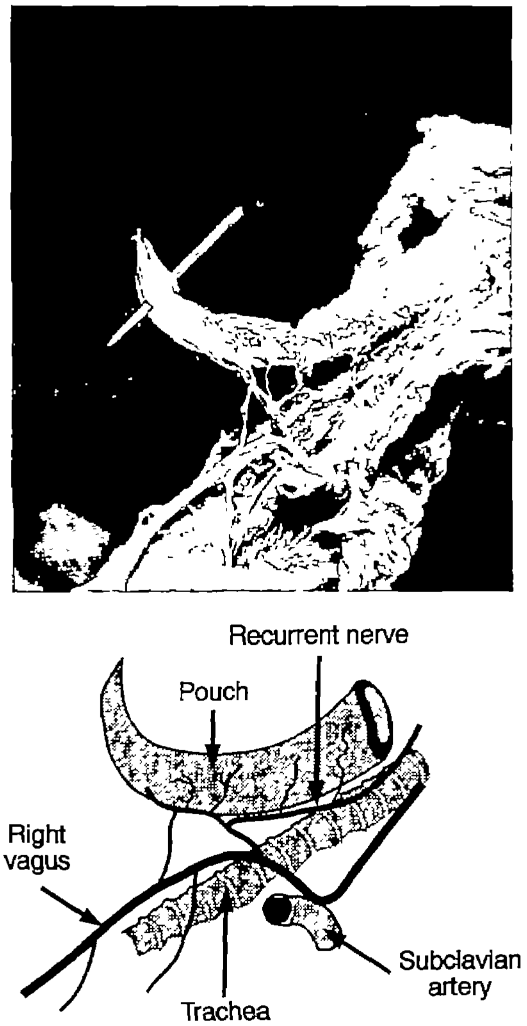

Fig. 2 Right vagus and right recurrent laryngeal nerve. The specimen is shown obliquely from the back with its craniad end to the right. The course of the right vagus nerve is shown; it has been misplaced to lie behind, instead of in front of, the cut end of the subclavian artery, the site of origin of recurrent laryngeal nerve. The atretic end of the mobilized oesophagus is held up by the probe. The nerve supply that it receives from the recurrent nerve is shown

segmental nerve supply, branches from the right and left recurrent laryngeal nerves, were divided.

Discussion

Deglutition occurs as a result of muscle contraction which involves a coordinated primary wave. It differs from peristaltic activity in other parts of the intestine in that the initial step is voluntary and involves striated muscles. Pharyngo-oesophageal contraction occurs without interruption to the wave of movement.

The vagus is the motor nerve to the oesophagus. In oesophageal atresia with distal fistula it has been shown that the atresia occurs at an anatomical watershed[6]. The proximal oesophageal pouch has striated muscles in its wall; the distal oesophagus has none. The central nerve stations for the nerve fibres that supply these muscles are different. Outside the brainstem the vagus nerves become confluent with the cranial roots of the accessory nerves. These fibres are found in the recurrent laryngeal nerves which supply the striated muscles of the pharynx and proximal oesophagus. They have their central origin in the nucleus ambiguus of the medulla oblongata. The remainder of the oesophagus is supplied by vagus nerve fibres which have their origin in the dorsal nucleus of the vagus. The transition from a striated to a smooth muscle tube does not occur abruptly. Histological evaluation established that, the tip of the pouch in the cadaver investigated contained striated muscle. In the event of the primary peristaltic wave emptying the oesophagus incompletely, a new and locally generated wave of contraction occurs. This contraction, induced by mural stretch receptors, is under the control of the intrinsic nerve supply of the oesophagus and is found only in the smooth muscle section. A single secondary peristaltic wave normally empties the oesophagus.

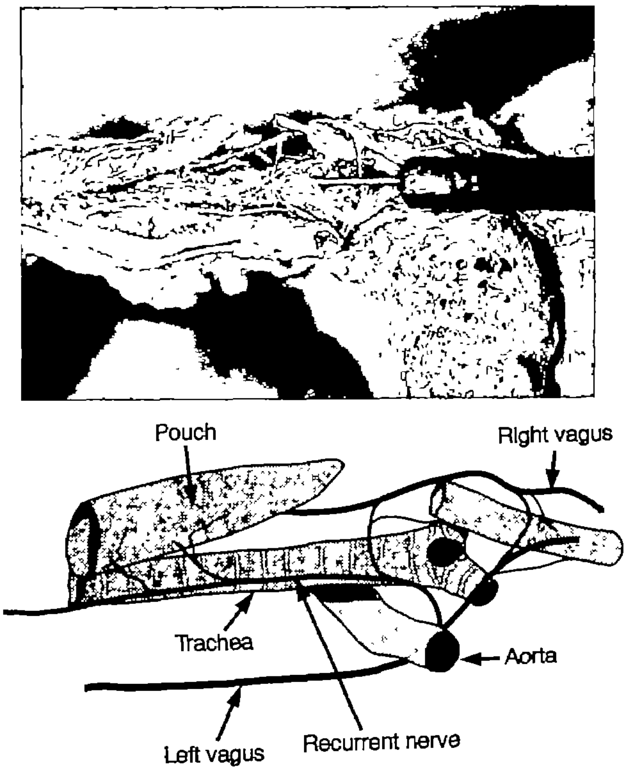

Fig. 3 Tracheo-oesophageal fistula. The specimen is in the prone position with the craniad end to the left. The tracheo-oesophageal fistula has been dissected free from the trachea at its bifurcation. Probes in the lumen of the oesophagus and the trachea mark the site of amputation. The relationship of the right vagus to this part of the distal oesophagus is shown as well as communicating branches between it and the left recurrent nerve and its parent nerve, the vagus

Since the first successful surgical repairs of oesophageal atresia were reported, abnormal swallowing has been documented[1,2,7,8]. When this occurs in patients in whom the operation was technically successful, it is attributed to a congenital cause. Abnormalities of the intrinsic nerve plexus have been reported[9] but the prevalence and role played by a congenital deficiency in postoperative dysphagia is not clear[10]. In a recent study which compared oesophageal peristaltic activity before and after surgery for atresia it was concluded that the motor abnormality resulted directly from the surgery[11]. The findings of the present study partially support this statement. During mobilization of the proximal oesophageal pouch it was shown that most of its extrinsic nerve supply was interrupted, the devastating consequences of which are well known. Oropharyngeal dysphagia (transfer dysphagia) is not commonly reported in these patients[1]. Skeletal muscle dysfunction is manifest by preoesophageal dysphagia and tracheal aspiration which are due to pharyngeal dysfunction[12]. In oesophageal atresia the pharynx is unaffected by surgery and whether the loss of proximal oesophageal function alone causes symptoms remains uncertain.

Studies that evaluated function in repaired atresia confirm the almost universal incidence of motor abnormality affecting swallowing[1,2,7,13,14]. The immediate perianastomotic portions and the most proximal part of the distal oesophagus, the segments most mobilized during surgery, are the most severely affected[2]. Early reports emphasized the presence of distal oesophageal dysmotility. However, more recent studies indicate that this is more universal and that the proximal original pouch segment rarely contracts normally.

The oesophageal segments have to be mobilized during the repair. Extensive pouch mobilization is associated with severe motor disability. This is seen in patients who have had an oesophagostomy[13]. Although it has been established that deprivation dysphagia can partly be prevented by sham feeding, which aims to teach the person to initiate a primary peristaltic wave, motor nerve disruption must be a major component of this problem. Complete mobilization of the proximal pouch should be avoided, although the anastomosis must not be compromised. Mobilizing the distal oesophagus to obtain additional length could also have its consequences. Dysphagia of the transport type with or without gastro-oesophageal reflux could result[15]. Feeding difficulties are a major problem after repair in oesophageal atresia[14], although these symptoms tend to disappear with time[7].

Small intestinal myoelectrical activity and bacterial flora after Roux-en-Y reconstruction

E. SCHIPPERS, S. WILLIS, G. RUCKDESCHEL* and V. SCHUMPELICK

*Department of Surgery, Universitatsklinikum Rheinish Westphalian Technical University Aachen and *Max von Pettenkofer Institute for Hygiene and Medical Microbiology, Klinikum Großhadern, Ludwig Maximillian Universität Munich, Germany*

Correspondence to: Dr E Schippers, Department of Surgery, Universitatsklinikum Rheinish Westphelian Technical University Aachen, Pauwelsstrasse 30, 52057 Aachen, Germany

Small bowel myoelectrical activity and intestinal microflora were examined after partial gastrectomy and Roux-en-Y reconstruction in six dogs. Bacteriological analysis revealed a predominance of faecal bacteria. The basal electrical rhythm of the Roux limb was significantly decreased, while the frequency of phase III was increased ($P<0·05$). In the bypassed duodenum, activity fronts occurred in only 25 per cent of experiments. Food intake led to an increase in the mean(s.e.m.) motility index in the Roux limb (from 46·1(9·4) to 75·0(21·5), $P<0·05$), but not in the bypassed intestine (from 27·0(3·6) to 27·8(4·1), P not significant). Stimulation of the hypomotile bypassed intestine with cisapride induced an increase in the motility index from 27·0(3·6) to 111·2(16·5) ($P<0·001$).

The Roux-Y reconstruction is a common procedure in gastric and biliary surgery. The purpose of this reconstruction is to protect the oesophagus, gastric remnant or bile duct from nutrient or bile reflux by the propulsive peristalsis of the Roux limb. Nevertheless, after this technique some patients develop a symptom complex consisting of nausea, vomiting and, particularly, postprandial abdominal pain, the so-called 'Roux-Y syndrome'[1,2]. It has been hypothesized that these clinical symptoms are related to long-term changes in intestinal motility patterns accompanied by bacterial overgrowth in the upper gastrointestinal tract. Disturbed intestinal motility patterns in the fasting and postprandial state have been demonstrated in these patients[1]. Furthermore, Roux-en-Y reconstruction is often complicated by bacterial overgrowth[3,4].

The aim of the present experimental study was to examine the long-term changes in small intestinal myoelectrical activity after two-thirds gastric resection and Roux-en-Y reconstruction, and to determine consecutive changes in the bacterial flora in the upper gastrointestinal tract. A further aim was to examine the effect of a prokinetic agent on potentially disturbed motility patterns.

Materials and methods

Surgical procedure

After review and approval by the Animal Welfare Committee of the German government these experiments were performed under combined inhalation and intravenous anaesthesia (fentanyl–halothane) in male dogs weighing 10–15 kg In six dogs a median laparotomy was performed followed by two-thirds resection of the stomach. The duodenum was closed and intestinal continuity restored by a gastrojejunostomy with a jejunal loop, called the Roux limb. The duodenum and proximal jejunum were reanastomosed with the Roux limb 30 cm distal to the gastrojejunostomy by an end-to-side enteroenterostomy, forming a blind loop (*Fig. 1*). To monitor myoelectrical activity, six bipolar silver–silver chloride electrodes were implanted at equal distances (15 cm) on the serosal layer of the gastric remnant and the Roux limb, and two further electrodes were placed on the serosa of the bypassed intestine (*Fig. 1*). The cables led out of the abdomen on the left side and were brought subcutaneously to the interscapular region. They were connected to a recording plug fixed to a jacket. Four dogs with an intact

gastrointestinal tract served as controls. They underwent implantation of eight electrodes at corresponding positions to the animals with a Roux limb.

Electromyography

Because of a strong correlation between myoelectrical and mechanical activity in the small intestine[5], electromyography was used to monitor motility patterns. Electrical signals were amplified and recorded online on an eight-channel polygraph (Hellige, Freiburg, Germany) with a paper speed of 5 mm/s. To identify the electrical spiking activity and the basal electrical rhythm (BER) a time constant of 0·03 s and an upper frequency limit of 30 Hz was chosen.

Visual analysis was carried out by two independent investigators. When analysis of a particular tracing differed between the two investigators, tracings were reviewed by both investigators together and a final common judgement was stated. For analysis, the appearance and periodicity of the migrating myoelectrical complex (MMC)[6], the duration of activity fronts (phase III), the propagation velocity of phase III and the calculated length of the activity front (duration × progression velocity) were determined. The various phases of the MMC in the interdigestive period were identified using the criteria of Code and Marlett[7] In addition the BER and its changes in each intestinal segment were determined. The postprandial 'fed pattern' was defined as random spiking activity and absence of the MMC[8]. For quantitative evaluation of different intestinal segments a myoelectrical motility index, defined as the number of spike potentials × spike width per 300 s, was calculated.

Experimental design

After a 2-week recovery period the myoelectrical activity of each animal was recorded five times in the fasting and postprandial period. For postprandial experiments a standardized (126 kJ (30 kcal) per kg body-weight) commercial meal (Waltham, Verden, Germany) with equal portions of fat, protein and glucose was used. The quantity of the test meal was calculated by the caloric value of the food (expressed as kcal per g food) and the body-weight of the dog. The meal was injected via an oro-oesophageal tube after identification of the first phase III of the MMC. Subsequently intestinal myoelectrical activity was recorded for 4 h The pharmacological effects of cisapride, a prokinetic agent, were also examined five times in every dog by injecting a bolus of cisapride 0 3 mg/kg intravenously after identification of the first phase III of the MMC Myoelectrical activity was recorded for two further periods of the MMC The experiments lasted for 6 months in each dog.

Bacteriological studies

For determination of the original bacterial flora in the upper gastrointestinal tract, a 1 × 1 cm^2 biopsy specimen from the stomach, duodenum and proximal jejunum was taken during operation in each dog Six months later, after termination of electromyographic recordings, a further laparotomy was performed and two biopsy samples from different locations of the same segments were taken. These were transported under anaerobic conditions (Port-A-Cul; Becton Dickinson, Heidelberg, Germany) to the microbiological laboratory and were cultured within 2 h. The biopsies were vigorously washed with stool buffer and the fluid obtained was inoculated with a spiral plater on various agar media selective for the main aerobic and anaerobic constituents of intestinal flora. The plates for aerobic organisms were incubated for 2 days, and those for anaerobes for up to 7 days until colonies were counted and identified. For quantitative evaluation, results were interpolated for up to 1 g of intestine and 1 ml of stool buffer. Results were given as $\log_{10}$ colony forming units (c.f.u.) of the various micro-organisms per gram of intestinal tissue. If the quantity in a single experiment was too small for evaluation, the detection threshold of the method, which was 1·0, was used.

Statistical analysis

Statistical analysis was performed with Friedmann's analysis or the Wilcoxon–Mann–Whitney *U* test as appropriate. $P<0\cdot05$ was considered significant. Results are given as mean(s.e.m.).

Results

All dogs survived the operation and remained healthy throughout the study period.

Basal electrical rhythm

The BER could be demonstrated constantly in every dog at every electrode. Its mean(s.e.m.) frequency was 18·5(0·5) per min in the duodenum, 14·0(0·2) per min in the Roux limb and 13·9(0·2) per min in the more distal jejunum. In comparison with controls there were no differences in the BER of the duodenum, whereas that of the proximal jejunum, the Roux limb, was significantly decreased (*Table 1*).

Fasting myoelectrical activity

The fasting myoelectrical activity of the small intestine was characterized by the periodic occurrence of the MMC in all dogs. After Roux-en-Y reconstruction a total of 135 MMCs with clear identification of phase III activity were registered. The activity fronts started below the gastroenterostomy and propagated aborally. Some 92 per cent of activity fronts registered at electrode E2 reached the distal electrode E6, and only 8 per cent terminated earlier.

Following the Roux operation there was a significantly increased frequency of phase III of the MMC. The mean(s.e.m.) interval between two periods of phase III activity was 64·4(3·1) *versus* 110·9(15·0) min in the control group (*Table 2*). Interindividual and intraindividual variations in duration, in propagation velocity and in the calculated wavelength of phase III were small. Differences from controls were not statistically significant (*Table 2*). In

contrast to the Roux limb and the distal jejunum, where the four phases of the MMC could be identified easily, almost no periodic MMCs occurred in the bypassed duodenum. During 135 registrations of phase III activity propagating from E2 to E6, distinct activity propagating from E7 to E8 was observed in only 23 recordings. A non-propagating phase III-like activity at E8 was observed in 11 recordings ($P < 0·01$). These activity fronts observed in the duodenum terminated at the enteroenterostomy.

Quantitative evaluation of myoelectrical motility patterns showed a corresponding picture. The calculated mean(s.e.m.) motility index was 46·1(9·4) in the Roux limb and 33·9(4·9) in the distal jejunum ($P < 0·05$). The motility index of the duodenum was significantly lower at 27·0(3·6) ($P < 0·001$) (*Fig. 2*).

Postprandial myoelectrical activity

Immediately after instillation of a standard meal, a 'fed pattern' could be observed in controls and in Roux dogs in the Roux limb and in the distal jejunum. The MMC was completely interrupted and substituted by a strong irregular spike activity in all segments. In 32 of 35 experiments this 'fed pattern' was persistent until the end of the experiment, when there was reappearance of the MMC in three cases. In the bypassed duodenum there was also a visible change in motility pattern. Because clear identification of the single phases of the MMC was not possible, even before food intake, this change was not so evident. Quantitative evaluation showed a significant 63 per cent postprandial increase in the mean(s.e.m.) motility index of the Roux limb from 46·1(9·4) to 75·0(21·5) ($P < 0·05$). In the jejunum there was a 36 per cent increase from 33·9(4·9) to 46·1(7·0) ($P < 0·05$), whereas there was no change in the duodenum (fasting 27·0(3·6) *versus* postprandial 27·8(4·1), P not significant) (*Fig. 2*).

Effect of cisapride

Intravenous injection of cisapride in a dose of 0·3 mg/kg induced strong spike activity in all intestinal segments. This effect could be demonstrated immediately after injection in all segments at the same time. This increase in spike activity was not as regular as the aboral propagation of spike activity in phase III of the MMC. Quantitative evaluation showed an increase in the motility index from twofold to 12-fold that of the controls. The mean(s.e.m.) motility index after application of cisapride was three to four times higher in all animals (*Fig. 2*): 144·2(11·1) in the Roux limb, 92·4(13·9) in the jejunum and 111·2(16·5) in the duodenum ($P < 0·001$).

Bacterial flora

Biopsies from the gastrointestinal wall taken during the two-thirds resection of the stomach and Roux-en-Y reconstruction served as controls. Bacteria were not detected in all specimens and, if present, only in very low numbers. Therefore control values were set to the detection threshold of the method at 1·0 c.f.u. In contrast,

Table 4 Differentiation of bacterial species in the upper gastrointestinal tract 6 months after Roux-en-Y reconstruction

	Colony-forming units			
Bacterial species	Stomach	Roux limb	Distal jejunum	Duodenum

Values are mean (range) of two biopsies from each intestinal segment

high numbers of organisms were detected in the stomach, Roux limb, jejunum and duodenum 6 months after operation. Quantification of bacterial colonization showed differences depending on the intestinal segments from which the biopsies had been taken. The highest numbers of micro-organisms were found near the gastrojejunostomy with 7·1 c.f.u., and the lowest were in the gastric fundus with 3·8 c.f.u. ($P<0\cdot05$). There were no significant differences in bacterial counts between Roux limb, duodenum and jejunum (*Fig. 1*). The increase in the bacterial flora was similar in aerobic and anaerobic bacteria (*Table 3*), with *Bacteroides* species, *Clostridia* and non-sporing Gram-positive rods such as bifidobacteria and eubacteria growing as anaerobes and *Escherichia coli*, enterococci and lactobacilli as aerobes (*Table 4*).

Discussion

Disturbed intestinal motility occurs in patients who have undergone Roux-en-Y reconstruction. Mathias *et al.*[1] described a 'Roux-Y syndrome', which is characterized by chronic abdominal pain, constant nausea and intermittent postprandial vomiting. Gustavsson and co-workers[9] evaluated patients with Roux-en-Y reconstruction retrospectively for these symptoms. Although they reported excellent functional results in about two-thirds of all patients, 30 per cent of those with gastrojejunostomy and 8 per cent with oesophagojejunostomy suffered from the Roux-Y syndrome. Scintigraphic studies in humans after Roux-en-Y reconstruction have shown normal[2] as well as delayed[10–12] or accelerated[11] emptying. The results of manometric studies in symptomatic patients after the Roux operation, demonstrating disturbed interdigestive motility without regular MMCs and the absence of a 'fed pattern' in symptomatic patients, are, however, more definite[1,12–14].

In electromyographic recordings after Roux-en-Y reconstruction in the present study, the activity front was propagated from the Roux limb to the distal jejunum without impairment. The increased frequency of the MMC in these dogs was in accordance with observations in patients after Roux-Y gastrectomy[15]. Food intake interrupted the MMC and led to the appearance of the typical 'fed pattern'. These data accord with reports of electromyographically normal intestinal motility in the Roux limb in asymptomatic patients[16].

Descriptions of retrograde propagation of jejunal electrical slow waves and spike bursts in dogs[17,18] and in symptomatic patients[19] suggest that these abnormalities might contribute to the Roux-Y stasis syndrome. A return of the BER was not observed in this study, possibly because the electrodes were too far apart. However, retrograde propagation of basal electrical activity has also been reported in intact dogs[17]. Nevertheless there was a significant decrease in the frequency of the BER in the proximal Roux limb, indicating that interruption of intestinal continuity might lead to loss of stimulation by the intestinal pacemaker in the duodenum[20].

In the present experiments there was a highly significant decrease in myoelectrical activity in the bypassed duodenum. Under fasting conditions, phase III activity could be identified clearly in only 25 per cent of experiments. After food intake there was also no adequate increase of electrical activity in the duodenum. This could be explained in part by exclusion of the duodenum. The direct contact of food with the duodenal mucosa as a decisive stimulus for postprandial motility is missing. Duodenal hypomotility could lead to delayed transport of bile and pancreatic enzymes, and consecutively to asynchronous gastric emptying and secretion of bile and pancreatic enzymes, inducing steatorrhoea, postprandial nausea and flatulence. In support of this hypothesis, Bradley *et al.*[21] demonstrated significantly decreased trypsin and lipase concentrations in the jejunum of patients with Roux-en-Y reconstruction.

Cisapride stimulated motility in all segments of the small intestine in the present experiments. In humans, stimulation of intestinal motility by cisapride occurs with accelerated intestinal transit[22]. Therefore, cisapride might be useful in the treatment of functional disorders in patients having Roux-en-Y reconstruction.

The long-term complications of gastric surgery, such as steatorrhoea, diarrhoea and impaired absorption of vitamin B_{12}, may be the result of abnormal proliferation of bacteria in the upper intestinal tract. In the present study overgrowth with a typical faecal flora of aerobic and anaerobic bacteria was observed. The dominant species were *Bacteroides* and *E. coli*, as reported previously[3,4,21]. Bacterial overgrowth may be facilitated by intestinal motility disorders. It has been hypothesized that the MMC can no longer fulfil its 'housekeeper' function[23]. Scintigraphic studies in patients with Roux-en-Y biliary–enteric anastomosis, demonstrating a hypomotile loop[24] and a high rate of cholangitis[25], are in accord with this theory. In the present study, however, demonstration of the same extent of typical faecal flora in the hypomotile duodenum and in the Roux limb cannot be explained by this theory alone.

Gastric stasis and reduction of acid production are also possible mechanisms for bacterial overgrowth in the upper gastrointestinal tract. In contrast to humans, the gastric mucosa of the dog possesses parietal cells in the fundus of the stomach, so that a two-thirds resection would not lead to achlorhydria. Furthermore, there are descriptions of achlorhydria in humans without bacterial overgrowth[3]. However, the remaining acid production of the gastric fundus could have been responsible for the relative decrease of bacterial overgrowth in this study.

Upper oesophageal sphincter function during general anaesthesia

J. P. McGRATH, C. McCAUL*, P. J. BYRNE, T. N. WALSH and T. P. J. HENNESSY

*University Departments of Surgery and *Anaesthesia, St James's Hospital, Dublin 8, Ireland*
Correspondence to: Mr T. N. Walsh

The effect of anaesthesia on the upper oesophageal sphincter response to acid in the distal oesophagus and hypopharynx, and the effect of atracurium besylate on acid migration into the hypopharynx, was studied in 102 patients undergoing elective varicose vein surgery. Group 1 ($n = 48$) received a general anaesthetic and the muscle relaxant atracurium besylate whereas group 2 ($n = 54$) received a general anaesthetic without relaxation. Upper oesophageal sphincter tone was significantly lower in patients receiving muscle relaxants ('sphinctometer output', eight *versus* 14, $P<0{\cdot}05$). Sixteen patients (16 per cent) had reflux into the distal oesophagus during anaesthesia (nine in group 1 and seven in group 2, P not significant), of whom seven had reflux to the hypopharynx. There was no difference in incidence of hypopharyngeal acid exposure between groups. Upper oesophageal sphincter tone did not alter in response to reflux into the distal oesophagus or hypopharynx in either group. The upper oesophageal sphincter fails to protect the hypopharynx under general anaesthesia even if patients do not receive a muscle relaxant.

The upper oesophageal sphincter (UOS) is a high-pressure zone between the pharynx and oesophagus which helps protect the respiratory tract from aspiration of gastric refluxate and prevents entry of air into the oesophagus during inspiration[1,2]. Aspiration is a greater risk if gastric refluxate transgresses the UOS. During anaesthesia the risk of aspiration increases; this is thought to result from the effect of anaesthetic agents and muscle relaxants on the UOS, as most have been shown to reduce UOS pressure[3–6]. UOS pressure has been shown to increase in response to both gastro-oesophageal reflux and oesophageal acid infusion[7,8]. The effect of general anaesthesia and muscle relaxants on this response is unknown.

The UOS has proved difficult to study. There is considerable axial and radial asymmetry, explaining the variability of results using station perfusion manometry as pressure readings depend on the direction of the catheter, with higher pressures directed anteroposteriorly. The speed and range of movement of the sphincter make it almost impossible to maintain the position of the transducer or perfused catheter in the high-pressure zone for prolonged periods. The only system that hitherto allowed prolonged studies was the Dent sleeve but this is unphysiological and requires the patient to remain supine throughout the study[9,10]. With the development of solid-state circumferential transducer technology more accurate studies of UOS function are now possible[2].

The sphinctometer is a 6-cm oil-filled device that allows determination of sphincter tone[11]. It has been used previously for the study of lower oesophageal sphincter (LOS) function[12–15]. In this study it was employed to evaluate UOS function in response to muscle paralysis and oesophageal acid reflux. The effect of muscle paralysis on the pattern of gastro-oesophageal reflux into the distal oesophagus and hypopharynx under anaesthesia was also examined.

Patients and methods

All patients admitted for elective varicose vein surgery over a 6-month period were invited to participate in the study. All were American Society of Anesthesiologists grade I or II. Patients receiving any medication 24 h before surgery, those with a history of previous upper gastrointestinal surgery and those requiring laryngeal mask or epidural anaesthesia were all excluded from the study. The study was approved by the hospital ethics committee and informed consent was obtained from all participants.

Study groups

Patients were subdivided into two groups based on whether or not a muscle paralysing agent was used during anaesthesia. Group 1 ($n = 48$) received a paralysing agent in addition to general anaesthetic and group 2 ($n = 54$) received a general anaesthetic only. The decision to paralyse was based on the need for patients to have short saphenous vein surgery in addition to long saphenous vein ligation, and to be positioned prone for the second stage of the operation.

Median age was 32 years: 29 (range 19–67) years in group 1 and 34 (range 27–59) years in group 2 (P not significant). There were 33 women in group 1 and 30 in group 2 (P not significant).

Of 102 patients selected for the study 27 admitted to symptoms suggestive of gastro-oesophageal reflux. This included heartburn in 16, regurgitation in four, and heartburn and regurgitation in seven. Eight of these 27 patients took occasional medication, which included antacids in five and H_2-receptor antagonists in three. All described symptoms as mild and intermittent except one patient who had completed two courses of antacids. No patient recruited for the study was receiving medication at the time of admission to hospital. The 27 patients were randomized to groups 1 and 2 based on the need for short saphenous vein surgery. In this manner 15 were randomized to group 1 and 12 to group 2 (P not significant). For the purpose of this study, only recordings made during the initial supine period were analysed. All patients were studied in the supine position with the head on a single pillow.

Anaesthesia

Premedication consisted of diazepam 10 mg orally 40 min before surgery. Propofol 2·0–2·5 mg/kg, fentanyl 1 mg/kg and suxamethonium 1 mg/kg were given intravenously at induction. Anaesthesia was maintained with nitrous oxide and isoflurane. Atracurium 0·05 mg/kg was given to patients requiring a paralysing agent and morphine 2·5 mg was administered intravenously immediately before the incision was made.

pH measurement and manometry

A lubricated split rubber tube was passed orally into the

Paper accepted 11 December 1995

oesophagus. The sphinctometer and two antimony probes were passed through the rubber tube into the stomach. A pH less than 2 confirmed placement of the probes in the stomach. After allowing approximately 5 min for stabilization of the sphinctometer at body temperature, it was slowly withdrawn and the high-pressure zone (HPZ) of the LOS was identified and pressures recorded. Withdrawal of the sphinctometer into the oesophagus was followed by localization of the HPZ at the UOS. The area of highest recording within this HPZ was taken at the UOS Following identification of the sphincters the antimony probes were placed 5 cm above the LOS and 2 cm above the UOS, and the study commenced.

The sphinctometer gives a reading that is directly proportional to sphincter tone and is measured as 'sphinctometer output' (SO)[11]. Readings were taken until reversal of anaesthesia or until patients requiring short saphenous surgery were placed in the prone position.

Data analysis

Data were stored during the study on a motility digitrapper (Synectics, Stockholm, Sweden) and dual-channel pH digitrapper mark II (Synectics), downloaded on to a personal computer and analysed with Gastrosoft Software (Synectics). Results were expressed as median and range. The Mann–Whitney *U* test was used to compare groups.

Results

Data from 102 patients (63 women) with a median age of 32 (range 19–67) years was evaluable. Median study duration was 44 (range 22–117) min (*Table 1*). Thirty-two patients were lost from the study because of violation of the anaesthesia protocol (19), failure of intubation (seven), gastric pH greater than 2 (three) and sphinctometer drift (three).

Sixteen patients had reflux into the distal oesophagus. In nine of these reflux was documented in the distal oesophagus only; these patients were termed 'distal refluxers'. In seven the refluxate migrated proximally to the hypopharyngeal region and these patients were termed 'hypopharyngeal refluxers'. All pharyngeal reflux episodes were preceded or accompanied by a drop in pH to less than 4 in the distal oesophagus. There was no significant difference in the incidence of either distal (19 *versus* 13 per cent) or hypopharyngeal (6 *versus* 8 per cent) reflux between patients receiving and those not receiving muscle relaxants. The presence of symptoms suggestive of gastro-oesophageal reflux was not predictive of reflux episodes under general anaesthesia. The incidence of oesophageal reflux was similar in those with and without symptoms: four of 27 compared with 12 of 75 patients. The incidence of hypopharyngeal reflux was also similar: two of 27 symptomatic compared with five of 75 asymptomatic patients (*P* not significant).

Table 1 Reflux episodes and sphincter tone

	Paralysed ($n = 48$)	Non-paralysed ($n = 54$)
No. of patients with distal reflux*	9 (19)	7 (13)
No. of patients with hypopharyngeal reflux*	3 (6)	4 (7)
Upper oesophageal sphincter tone (SO)†	8 (4–11)	14 (10–19)‡
Lower oesophageal sphincter tone (SO)†	10 (8–14)	9 (6–15)
Duration of study (min)†	42 (24–95)	49 (22–117)

*Values in parentheses are percentages; †values are median (range). SO, 'sphinctometer output'. ‡$P < 0{\cdot}05$ *versus* paralysed (Mann–Whitney *U* test)

Median UOS tone was 14 (range 0–22) SO. It was significantly lower in patients receiving a paralysing agent (8 (range 4–11) SO) than in those not receiving a muscle relaxant (14 (range 10–19) SO) ($P < 0{\cdot}05$). UOS tone was not affected by reflux into the distal oesophagus or the hypopharynx. No change or alteration in UOS recordings was noted before, during or after reflux episodes. Median LOS tone was 9 (range 6–15) SO. Patients with hypopharyngeal reflux showed no difference in UOS tone, LOS tone or distal oesophageal acid exposure compared with those with distal oesophageal reflux alone.

Discussion

The patterns of gastro-oesophageal reflux under general anaesthesia reported in the literature are difficult to interpret because of variability in incidence, ranging from 0·5 to 42 per cent. This may reflect differing study populations, surgical and anaesthetic practices, or recording and interpretive techniques[16–18]. The incidence of 16 per cent (16 of 102) in this study is lower than that reported by others but as this study population was homogeneous and without significant morbidity it may reflect a true incidence. Seven of the 16 patients with distal gastro-oesophageal reflux also had migration of acid into the hypopharynx. The overall incidence of hypopharyngeal reflux was therefore 7 per cent. Proximal migration of refluxate may reflect compromised clearance mechanisms such as pharyngeal swallowing and secondary oesophageal peristalsis which are known to be impaired by anaesthesia[19,20].

The relationship between gastro-oesophageal reflux and UOS function in the waking state is unclear. Hunt *et al.*[7] reported that UOS pressures were significantly higher in patients with gastro-oesophageal reflux than in normal subjects. Others[21,22] have shown that intraoesophageal acidification may lead to increased UOS pressure. A number of studies, however, have failed to demonstrate such a rise in pressure[8,23]. In addition, studies that examined reflux episodes as opposed to oesophageal acidification have failed to demonstrate an UOS response to reflux[21,22,24]. These differences may reflect the limitations of previously available recording techniques which have relied exclusively on perfusion manometry. In this study the UOS showed no response to either distal oesophageal or hypopharyngeal reflux episodes during general anaesthesia. This has not been demonstrated previously.

Muscle relaxants had no effect on LOS pressure. This is consistent with previous studies showing that the LOS is not affected by atracurium besylate, or other non-depolarizing muscle relaxants, as it is composed of smooth muscle[27]. Consequently there was no detectable difference in distal oesophageal acid exposure in those receiving muscle relaxation. In contrast, the pressure of the UOS is significantly lower in patients receiving muscle relaxants[28]. This is consistent with the known actions of atracurium besylate on striated muscle.

Muscle relaxants did not increase the incidence of hypopharyngeal reflux. It is not clear why refluxate crossed the UOS into the hypopharynx in some patients. Distal oesophageal acid exposure was similar in both distal and hypopharyngeal refluxers. In addition, sphincter pressures did not differ significantly.

Oesophageal reflux migrates to the hypopharyngeal region in a significant proportion of patients. The oesophageal body and sphincters fail to protect the hypopharyngeal region. In spite of the absence of pharyngeal activity in these patients the duration of hypopharyngeal reflux episodes was very short. As clinical complications occur infrequently it is likely that other mechanisms such as salivary or bicarbonate secretion act as protective mechanisms. With migration of more than 40 per cent of reflux episodes into the hypopharynx, UOS function is compromised by anaesthesia and affords little protection from aspiration.

Ninety patients with carcinoma of the hypopharynx underwent pharyngolaryngectomy and reconstruction with a jejunal free autograft. Fifty-five patients had primary surgery and 35 salvage surgery for recurrence after radiotherapy. Following primary surgery 28 patients had postoperative radiotherapy and 27 did not. Complications occurred in 51 per cent of patients, the most common being necrosis of the jejunal graft (19 per cent); 12 per cent developed significant stenosis and 4 per cent died in the perioperative period. Eleven per cent of patients developed a fistula. The total number of complications diminished as the experience of the unit increased. Median follow-up was 4·9 years. Of patients treated with primary surgery, 48 per cent developed primary site recurrence (at 3 years) and 53 per cent neck node recurrence (at 5 years). The tumour-specific 5-year survival rate for all patients was 42 per cent. Following primary surgery 28 per cent survived for 5 years and after salvage surgery the rate was 59 per cent. Positive resection margins and extensive neck disease adversely affected survival ($P = 0{\cdot}02$ and $P = 0{\cdot}001$ respectively). The free revascularized jejunal graft is a safe and predictable method of repair following total pharyngolaryngectomy.

Carcinoma of the hypopharynx is a rare disease with an incidence in the UK[1] of approximately 1 in 100 000. Individual experience with this condition is often limited and treatment may be substandard with correspondingly poor results.

Hypopharyngeal carcinoma generally has a poor prognosis even with aggressive treatment and most patients are dead within 1 year of diagnosis[2]. Because of the low survival rate, high recurrence rate and generally high treatment morbidity, the choice of therapy is particularly important. Early hypopharyngeal cancer may be treated by irradiation, with the option of salvage surgery if recurrence supervenes[3–7]. It has been stated that radiotherapy should be reserved for patients without enlarged lymph nodes[8] but it has also been suggested that radiotherapy can be given for a small primary tumour and radical neck dissection subsequently performed for nodal metastases[6,7,9]. Surgical resection is preferred for large tumours or in the presence of bulky cervical metastases[10,11].

Small posterior pharyngeal wall tumours can be resected via a lateral pharyngotomy with preservation of the larynx[12,13]. More extensive and circumferential lesions require total pharyngolaryngectomy. A variety of techniques of pharyngeal reconstruction have been described but interposition of stomach, small bowel or colon[14–16] is considered the best option. This paper presents a large series of over 10 years' experience with the free jejunal graft for pharyngeal reconstruction after pharyngolaryngectomy for carcinoma which many consider the superior method of repair[17–23].

Patients and methods

Ninety patients were included in the study. Fifty-five received surgery as primary treatment, 28 had postoperative radiotherapy and 27 had none. No patient had planned combined treatment with preoperative radiotherapy. Thirty-five patients were treated with primary irradiation with curative intent and later developed a local recurrence which was managed by pharyngolaryngectomy and jejunal loop repair.

The stage of the tumour at presentation was determined using the Union Internacional Contra La Cancrum classification[24], and the general physical condition with the method recommended by the Eastern Cooperative Oncology Group[25]. Histological grade was assigned into well, moderately or poorly differentiated squamous cell carcinoma but in some cases no grade was given. All data were stored on a microcomputer database and the date of death and follow-up times recorded from clinic visits, general practitioner records, the Merseyside and Cheshire Cancer Registry, and Office of Population Censuses and Surveys data. No patient was lost to follow-up.

The technique of total pharyngolaryngectomy has been described elsewhere[26], as has the method of free revascularized jejunal loop repair[27]. Frozen-section histological examination of the resection margins has been carried out routinely only for the past 5 years. Before that it was performed only when clinically appropriate.

Briefly, the harvested segment of jejunum was usually based on the second jejunal artery and vein. The graft was interposed between the pharynx and upper oesophagus, the lower anastomosis was made with 3·0 polyglactin placed as a single layer of approximately 12 interrupted sutures, and the upper anastomosis was performed with a continuous single layer of 3·0 polyglactin suture, locked regularly. The anterior wall in proximity to the base of the tongue was reinforced with interrupted polyglactin sutures. The microvascular anastomosis was made in all cases using 9 0 monofilament polypropylene sutures using the 120° technique. Donor arteries were usually superior thyroid or lingual, and occasionally the facial. The donor vein was usually the external jugular, or a convenient branch of the internal jugular or superior thyroid veins. If none of these was available, the internal jugular vein itself was utilized by an end-to-side technique. All patients received intravenous antibiotics (usually cefuroxime and metronidazole) and all had dextran 40 (500 ml daily for 3 days).

When postoperative radiotherapy was employed, the dose ranged from 55 Gy given over 15 fractions to 60–66 Gy given as 25 to 35 fractions. The patient was immobilized in a beam-

Paper accepted 3 December 1995

directing plastic shell and treated using anterior oblique double-wedged fields.

Data were transferred from the database to the SAS statistical package on a Pentium microcomputer (Statistical Analysis System, version 6 03; SAS Institute, Cary, North Carolina, USA)[28]. Various host and tumour factors were included in the analysis (*Table 1*)

Categorical data were displayed in contingency tables and analysed by χ^2 test with Yates correction. Factors associated with complications were analysed by categorical modelling (the CATMOD procedure)[28] and the same method was used to analyse differences between patients receiving radiotherapy or no radiotherapy Survival curves were constructed using the life-table method[29] with the LIFETEST procedure[28] and differences in survival curves analysed with the log rank test[28,30]. While crude recurrence rates are given, actuarial development of recurrence is also quoted using the life-table method (LIFETEST)[28] The calculations are given only for the patients treated by primary surgery, as all those who had primary radiotherapy developed recurrence Factors associated with survival were further analysed by means of Cox's proportional hazards model[31].

Results

The study included 90 patients treated by total pharyngolaryngectomy and free revascularized jejunal loop repair. All but 13 procedures were done for carcinoma of the hypopharynx. Of the remainder, ten had carcinoma of the cervical oesophagus and three carcinoma in a pharyngeal remnant following total laryngectomy. All but two procedures were done for squamous cell carcinoma. Median hospital stay was 16 (range 11–90) days. Median potential follow-up was 4·9 years.

Host and tumour factors for the primary surgery ($n = 55$) and salvage surgery ($n = 35$) groups are detailed in *Table 1*. The salvage surgery group contained significantly more patients with carcinomas at sites other than the hypopharynx, for example cervical oesophagus or pharyngeal remnant ($\chi^2 = 15{\cdot}67$, 3 d.f., $P = 0{\cdot}001$). There was no difference in nodal status between patients having primary or salvage surgery at the time of primary treatment, i.e. surgery or radiotherapy. There was a significant difference between the tumour stage of the two groups at the time of surgery. There were fewer patients with neck node metastases at the time of primary site recurrence in patients having salvage surgery ($\chi^2 = 5{\cdot}89$, 1 d.f., $P = 0{\cdot}02$). In addition, patients in the salvage surgery group suffered fewer recurrences at the primary site than those in the primary surgery group ($\chi^2 = 4{\cdot}15$, 1 d.f., $P = 0{\cdot}04$).

Patients who had primary surgery followed by no adjuvant treatment were compared with those who had primary surgery followed by radiotherapy. Significant difference in clinical details existed only for sex: patients who had postoperative radiotherapy were mostly men ($\chi^2 = 5{\cdot}60$, 1 d.f., $P = 0{\cdot}02$).

ECOG, Eastern Cooperative Oncology Group; UICC, Union Internacional Contra la Cancrum; Post wall, posterior pharyngeal wall. *$P < 0{\cdot}05$ *versus* primary surgery (χ^2 test)

The actuarial development of recurrence at the primary site and in neck nodes for patients treated by primary surgery is shown in *Fig 1* The recurrence rate at the primary site was 48 per cent at 3 years and in the neck 53 per cent at 5 years. *Fig. 2* shows the effect of adjuvant postoperative radiotherapy. At 2 years patients who had postoperative irradiation had a 27 per cent recurrence rate at the primary site compared with 35 per cent in those who did not. The differences were not, however, significant ($\chi^2 = 0{\cdot}50$, 1 d.f, $P = 0{\cdot}48$). At 2 years 24 per cent of patients who had postoperative radiotherapy developed a neck node recurrence compared with 31 per cent of those who did not ($\chi^2 = 0{\cdot}10$, 1 d.f., $P = 0{\cdot}75$).

Multiple logistic regression using categorical modelling demonstrated no significant host or tumour factors associated with recurrence either at the primary site or in the neck in patients who had primary surgery.

The complications for all 90 procedures are shown in *Table 2*. There were no significant differences in the complication rates between patients having primary or salvage surgery. The complication rate reduced as experience increased: the first 45 patients treated in this unit had a complication rate of 56 per cent whereas the

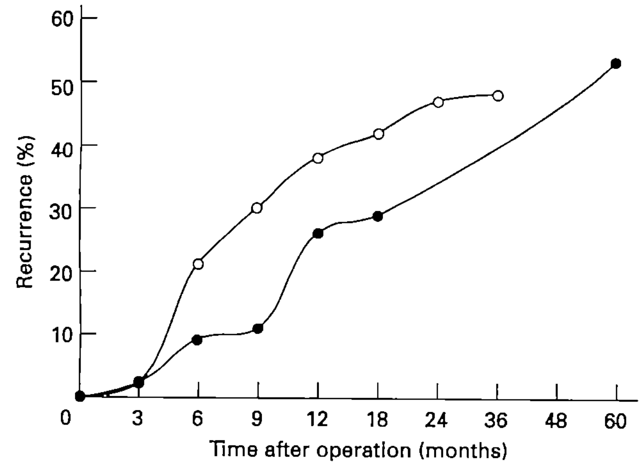

Fig. 1 Actuarial development of recurrence at primary site (○) and in neck nodes (●) in 55 patients treated by primary total pharyngolaryngectomy

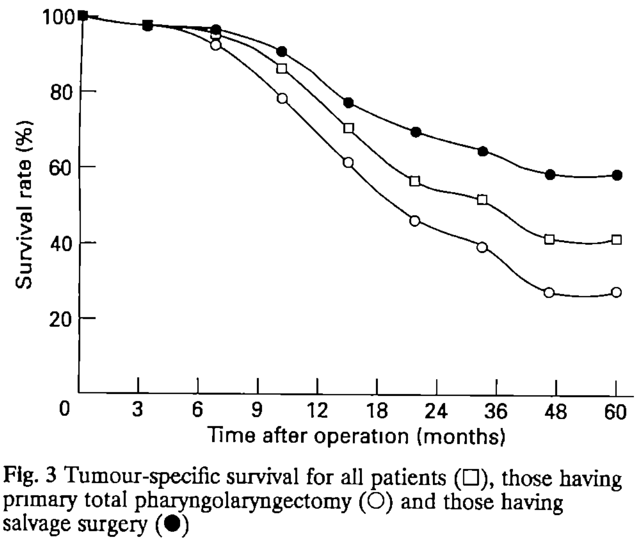

Fig. 3 Tumour-specific survival for all patients (□), those having primary total pharyngolaryngectomy (○) and those having salvage surgery (●)

most recent 45 had a rate of 47 per cent ($\chi^2 = 0{\cdot}40$, 1 d.f., $P = 0{\cdot}53$). Twelve per cent of patients developed stenosis severe enough to require dilatation. Sixty per cent were able to eat a reasonably normal diet, although not all could eat meat. No patient had complete dysphagia.

Table 2 Complications of total pharyngolaryngectomy with free revascularized jejunal loop repair

Complication	All patients* ($n = 90$)	Primary surgery ($n = 55$)	Salvage surgery ($n = 35$)	χ^2	d f	P

Table 3 Cox regression: factors affecting survival of 90 patients

Variable	Estimate	P
Age	−0·17	0·56
Sex	0·23	0·13
Site: postcricoid *versus* piriform fossa	0·43	0·25
Histological grade	0·30	0·12
Tumour stage	−0·33	0·09
Positive resection margin	−0·19	0·02
Performance status	0·19	0·32
Stage of neck node metastases	0·10	0·33
Histological stage of neck dissection	−0·13	0·001
Primary surgery *versus* primary radiotherapy*	1·67	0·0004

*Primary radiotherapy gave a better cure rate than primary surgery but this was a biased group as only patients with recurrence at the primary site were included, not those dying after radiotherapy

When patients who had stenosis before radiotherapy were excluded from the group of 55 patients having primary surgery there was no significant direct effect of radiotherapy on the rate of stenosis ($\chi^2 = 0{\cdot}96$, 1 d.f., $P = 0{\cdot}33$).

The graft necrosis rate was 19 per cent but results improved dramatically with experience. The rate was 31 per cent for the first 45 patients but fell to 4 per cent for the second 45.

Host and tumour factors associated with flap necrosis, fistulas and stenosis were analysed by multiple logistic regression; there were no significant associations.

Of patients having primary surgery, 27 had no neck node metastases whereas 28 had enlarged neck nodes at the time of surgery; in the salvage surgery group the values were 27 and eight respectively. Nearly all patients with neck node metastases were treated by radical neck dissection and all patients had positive histological results. Thirty-one of the 34 patients in the primary surgery group having treatment to the neck had a radical neck dissection; one patient had bilateral radical neck dissection, one an extended radical neck dissection and one a modified neck dissection. Extracapsular rupture was demonstrated histologically in 16 cases. Of patients who had primary radiotherapy, two had a radical neck dissection and two radiotherapy to the neck. Eight patients having salvage surgery also had radical neck dissection, three of them bilateral.

The observed survival rate of all patients at 5 years was 17 per cent (95 per cent confidence interval (c.i.) 9–26 per cent). Following primary surgery the survival rate was 11 (95 per cent c.i. 4–21) per cent, and after salvage surgery 29 (95 per cent c.i. 14–44) per cent. For all patients the tumour-specific survival rate was 42 (95 per cent c.i. 23–58) per cent. After primary surgery this was 28 (95 per cent c.i. 10–48) per cent and after salvage surgery 59 (95 per cent c.i. 31–78) per cent (*Fig. 3*).

The 3-year tumour-specific survival rate in patients who had postoperative radiotherapy was 32 per cent and in those who did not have radiotherapy it was 38 per cent ($\chi^2 = 0\cdot14$, 1 d.f., $P = 0\cdot71$).

Survival data were further analysed using Cox's proportional hazards model and the various statistics are tabulated in *Table 3*.

Discussion

This department started using the technique of free jejunal grafting in 1967 but had little success initially because of lack of experience in microvascular techniques. The present paper does not address the relative merits of surgery *versus* radiotherapy, as these have been covered in other publications from this unit[5–7,13].

The present study demonstrates that primary surgery tends to be used for cricopharyngeal cancer and radiotherapy for tumours in other sites. In addition, patients with more advanced tumours tend to have primary surgery, and those with early tumours have primary radiotherapy. There is a tendency for patients with neck node metastases to have surgery. The overall cure rate for hypopharyngeal cancer is relatively poor; half the patients in this series were dead within 18 months. It is not the policy of this department to carry out total pharyngolaryngectomy and repair with free revascularized jejunal loop as a palliative procedure in a patient known to be dying from the disease. Stringent efforts are made to stage the disease adequately, including computed tomography of the lungs, ultrasonography of the liver and bone scanning when bulky disease is present. Of patients who are potentially curable, only just over 40 per cent are actually cured by total pharyngolaryngectomy with free revascularized jejunal loop.

The complication rate is high: only 49 per cent of patients have no complications. This value, however, compares favourably with that from other series[32,33]. The fistula rate in the present series was low compared with that in others[22,34–38], as was the perioperative mortality rate (4 per cent)[32,35,39]. Sixty per cent of patients were able to eat a normal diet, but 12 per cent had stenosis severe enough to require endoscopic dilatation, similar to other studies[22,35,37,38,40,41]. Speech was not specifically studied in the present paper but is known to be relatively poor following jejunal repair[42]. Some 30 per cent of patients in whom tracheal oesophageal valve rehabilitation is attempted develop intelligible speech[43].

The primary site recurrence rate in the present series was 48 per cent after 3 years following which no further recurrences occurred. In the neck, recurrence occurred for up to 5 years, to reach an overall rate of 53 per cent. Radiotherapy appeared to reduce this recurrence rate at the primary site from 35 to 27 per cent, and the rate of neck node recurrence from 31 to 24 per cent.

Cure rates in the present series were satisfactory with a tumour-specific survival rate of 57 per cent at 2 years and 42 per cent at 5 years, which compares favourably with other series[23,32,35,44]. Patients who were treated by primary surgery had a poorer survival rate than those treated for recurrence after radiotherapy. The 5-year tumour-specific survival rate for patients having primary surgery was 28 per cent and for those receiving salvage surgery 59 per cent. Cox's regression analysis confirms this finding, which is difficult to explain (*Table 3*). Patients who had primary radiotherapy were a selected group. At the time of presentation they had disease of lesser volume than those undergoing primary surgery. Following radiotherapy, recurrence at the primary site occurred after a median interval of 18 months; in the primary surgery group median survival was similar. Patients submitted for salvage surgery are therefore in a favourable prognostic group.

Postoperative radiotherapy may reduce recurrence rates after primary surgery, although in this series the reduction was not significant. No effect was seen on survival. El-Bedawi *et al.*[45], however, did find a significant reduction in failure rate above the clavicles and an increase in survival when comparing surgery alone to surgery plus postoperative radiotherapy. Arguably, any hypopharyngeal cancer big enough to warrant primary surgery should also be treated with postoperative irradiation. Radiotherapy did not adversely affect complication rates and, in particular, was not implicated in the development of postoperative stenosis.

Presently, for patients with small hypopharyngeal tumours and no neck node involvement, radiotherapy is the treatment of choice; for those with small primary tumours and node metastasis, radiotherapy and radical neck dissection are employed. For larger tumours, where some of the pharynx can be saved, total laryngectomy and partial pharyngectomy is indicated. For larger tumours that have not spread to the thoracic oesophagus, total pharyngolaryngectomy and repair with a free revascularized jejunal loop is the treatment of choice. If this is not feasible, oesophagectomy is also carried out, followed by gastric transposition. The mortality rate associated with the latter procedure is, however, high compared with that of jejunal loop repair[32,46].

Acknowledgements

The authors would like to thank Mrs Brenda Cowley for typing the manuscript and Mrs Tracey Whittle for technical assistance with the tables and figures. This project was funded by a grant from the North West Cancer Research Fund. The authors also thank Professor P. M. Stell, who built up the database and who also carried out many of the surgical procedures

Laparoscopic surgery for gastro-oesophageal reflux: beyond the learning curve

D. I. WATSON, G. G. JAMIESON, R. J. BAIGRIE, G. MATHEW, P. G. DEVITT, P. A. GAME and R. BRITTEN-JONES

Correspondence to: Mr D. I. Watson

From September 1991 to October 1995, 320 Nissen fundoplications were undertaken laparoscopically by 12 surgeons at a single institution. To assess the performance of the procedure in the hands of five 'experienced' surgeons, the first 20 procedures performed by each surgeon or surgical trainee were excluded, providing a group of 174 patients for review. A short loose 360° fundoplication was performed in all instances, with short gastric vessel division performed in 35·0 per cent of patients and hiatal repair in 66·7 per cent. Median operating time was 80 (range 30–210) min and median postoperative stay was 3 (range 1–19) days. Sixteen procedures (9·2 per cent) could not be completed laparoscopically and required conversion to open surgery. Some 144 patients were reviewed by a scientific officer 3 months after surgery, 85 at 12 months, and 32 at 2 years, using a standard clinical questionnaire. All but one were free from reflux symptoms, although 20·1 per cent reported some dysphagia at 3 months' follow-up; this figure declined to 11 per cent at 12 months and 6 per cent (two of 34 patients) at 2 years. At each follow-up interval, 91 per cent of patients were satisfied with the outcome of the surgery. Objective testing with oesophageal motility (75 patients) and barium swallow (113) studies 3–6 months after surgery confirmed the clinical outcome. Complications occurred in nine patients (5·2 per cent); four (2·3 per cent) of these required a subsequent operation within 30 days of surgery for bleeding (one patient), paraoesophageal herniation (one) and dysphagia (two). A further procedure was necessary in six other patients (3·4 per cent) for late problems, including paraoesophageal herniation (two), hiatal stenosis (three) and gastric obstruction (one). Revision was performed laparoscopically in two patients. The clinical results of laparoscopic Nissen fundoplication by 'experienced' laparoscopic surgeons were comparable with those of open surgery.

Since the initial description of laparoscopic antireflux surgery in 1991[1,2], experience and expertise have been acquired rapidly in many centres, with several reports now describing experience of more than 100 procedures[3–7]. It is too early to assess the long-term results, which will be essential to evaluate the laparoscopic approach to surgery for gastro-oesophageal reflux.

The introduction of laparoscopic fundoplication has not been without difficulties; a number of complications specific to this procedure have been described. Problems have included reoperation for troublesome dysphagia[6,8], early postoperative paraoesophageal hiatus herniation[9], fibrous stricturing of the oesophageal hiatus[10] and visceral perforation[1,6,11]. Some of these problems may have resulted from inexperience during the evolution of the laparoscopic procedure, whilst others may result from modifications to established techniques aimed at making the laparoscopic approach easier to perform. Two postoperative deaths have also been reported[7,12].

Earlier reports included the 'learning curve' experience of each contributing surgeon introducing a potential bias when making a comparative assessment with open techniques. The authors' early experience with laparoscopic fundoplication has been reported elsewhere[4,5]. This was associated with a 10 per cent rate of conversion to open surgery, as well as a significant reoperation rate. The experience involved a major learning and training component, as these procedures were performed by seven consultant surgeons and four surgical trainees. To determine whether results have improved with subsequent experience, overall outcome was evaluated after excluding all patients operated on by a surgeon during the learning curve. This defined a group of patients whose surgery was performed by experienced surgeons only.

Patients and methods

From September 1991 to October 1995, 320 patients underwent laparoscopic Nissen fundoplication by one of 12 surgeons and trainees associated with the Royal Adelaide Centre for Endoscopic Surgery. All patients admitted for antireflux surgery were offered the laparoscopic approach, irrespective of any difficulties perceived by preoperative assessment such as obesity, large hiatal hernia, previous upper abdominal surgery, oesophageal stricture or Barrett's oesophagus. Data on preoperative assessment and management, surgical procedure and postoperative outcome for each patient were collected prospectively and stored on a computerized data base (FileMaker Pro; Claris Corporation, Santa Clara, California, USA). Patients had preoperative oesophageal manometry, and objective evidence of gastro-oesophageal reflux was confirmed by endoscopy and/or pH monitoring.

Postoperative clinical follow-up was obtained by the application of a standard questionnaire administered by a non-clinical scientific officer 3 and 12 months after surgery, and then annually thereafter. The presence or absence of heartburn, liquid and solid food dysphagia, as well as patient satisfaction with the procedure was graded from 0 to 10 using visual analogue scales. The presence or absence of gas bloat, ability to burp and ability to relieve abdominal distension, as well as the patient's willingness to undergo the same procedure again under similar preoperative circumstances, were also determined. Details of adverse outcomes such as hospital readmission, complications or surgical revision were recorded. Between 3 and 6 months after

Paper accepted 4 December 1995

surgery patients were encouraged to have repeat oesophageal manometry with testing for acid reflux, and a barium swallow examination. Endoscopy was reserved for symptomatic patients with clinical indications.

It was estimated that a surgeon's learning curve should comprise 20 procedures. This number was selected as preliminary experience suggested that the learning phase for laparoscopic fundoplication was longer than that for laparoscopic cholecystectomy[13,14]. The first 20 patients operated on by each surgeon who contributed to the overall departmental experience were excluded. This left a group of patients whose surgery was performed by 'experienced' surgeons. Patients who underwent another laparoscopic prcocedure at the same time as fundoplication were excluded from analysis.

The surgical technique used has been described in detail previously[4]. Five trocars were sited following Veress needle insufflation at the left costal margin. Both pillars of the oesophageal hiatus were dissected initially to expose the distal oesophagus and enable posterior hiatal repair when appropriate. Short gastric vessels were divided between clips in some patients before construction of a short loose fundoplication, calibrated over a 52-Fr bougie within the lumen of the oesophagus. Three or four interrupted polypropylene sutures were used to secure a total fundoplication of about 2 cm in length.

Results

Of the 320 patients who underwent the laparoscopic Nissen procedure, 140 operations were performed by surgeons who had completed 20 or fewer procedures. A further four patients had cholecystectomy and two had highly selective vagotomy at the time of laparoscopic fundoplication. Thus, 174 patients were identified who had surgery by five 'experienced' surgeons. These surgeons had performed 102, 64, 51, 39 and 27 procedures in their individual experience. There were 103 men and 71 women. Median age was 48 (range 15–82) years and weight 80 (range 51–120) kg. A sliding hiatus hernia was demonstrated before operation in 88 patients (50·6 per cent). Fifty-four patients (31·0 per cent) had undergone previous open abdominal surgery of whom 22 (12·6) had had upper abdominal surgery.

A total of 158 procedures were completed laparoscopically, while 16 (9·2 per cent) required intraoperative conversion to open surgery because of difficulties with the laparoscopic approach (*Table 1*). Median operating time was 80 (range 30–210) min. Short gastric vessels were divided in 61 patients (35·0 per cent), and the hiatus was narrowed with sutures in 116 (66·7 per cent). Median postoperative hospital stay was 3 (range 1–19) days.

Complications occurred in nine patients (5·2 per cent) within 30 days of surgery (*Table 2*). No respiratory morbidity was seen. Severe dysphagia was managed successfully by endoscopic dilatation in two patients, endoscopic retrieval of a food bolus in one and reoperation in two. The food bolus obstruction was associated with early consumption of large pieces of unchewed meat, despite specific instructions on avoidance. Early reoperation within 30 days of the original procedure was necessary in four patients (2·3 per cent), for acute paraoesophageal herniation (one), bleeding from a short gastric vessel (one) and dysphagia (two; one operation was achieved laparoscopically on the second day after fundoplication by removal and replacement of a single 'tight' suture). A later surgical procedure was required for a further six patients (3·4 per cent), between 2 and 11 months after the original surgery: two for paraoesophageal herniation (one revised laparoscopically at 6 months), three for stricture of the diaphragmatic hiatus resulting in dysphagia in spite of a demonstrably loose fundoplication, and one for gastric obstruction due to a poorly constructed fundoplication. Each of these complications has been described in detail elsewhere[9,10].

Table 1 Reason for conversion to open surgery

	No. of patients
Obesity	5
Large hiatus hernia	4
Adhesions	3
Perioesophagitis	2
Liver hypertrophy	1
Bleeding	1

Table 2 Postoperative complications

	No. of patients
Dysphagia	5
Paraoesophageal herniation	1
Deep vein thrombosis	1
Bleeding short gastric vessel	1
Pneumothorax	1

Barium swallow examination 3–6 months after surgery in 113 patients (64·9 per cent) confirmed an intact fundoplication in all those examined. However, delayed emptying of barium through the fundoplication was seen in seven patients (6·2 per cent), a finding that correlated with postoperative dysphagia. This was associated with either a presumed tight fundoplication (four patients) or narrowing of the oesophageal hiatus (three). A small paraoesophageal hernia was noted in a further three patients. This was symptomatic in two, requiring late surgical revision, while the other patient remains symptom free.

Oesophageal motility studies confirmed correction of acid reflux in all 75 patients examined after operation, and a rise in resting lower oesophageal sphincter pressure from a median of 7 (range 1–44) mmHg before operation to 22 (range 4–70) mmHg after surgery. Incomplete lower oesophageal sphincter relaxation was more likely in patients with postoperative dysphagia. The clinical outcome in the subgroup of patients who had postoperative testing was similar to that of the remaining patients who did not undergo these tests.

Clinical follow-up of greater than 3 months was available for 144 patients (82·8 per cent). At 3 months, all but one were free from all reflux symptoms (99·3 per cent). However, 29 patients (20·1 per cent) described dysphagia for solid foods. Using a visual analogue scale from 0 (totally unsatisfied) to 10 (totally satisfied), 131 patients (91·0 per cent) rated the surgical outcome as 7 or better. A score of 7–10 approximated grades 1 and 2 of a modified Visick scale used in other studies in this department. Some 132 patients (91·7 per cent) expressed willingness to undergo the same procedure again under identical preoperative circumstances.

Of the 85 patients (48·9 per cent) who have been followed for more than 12 months, all but one (99 per cent) are free from reflux symptoms. Nine (11 per cent) report some dysphagia for solid food and 77 (91 per cent) rated the operation as 7 or better on the visual analogue scale of satisfaction. Thirty-two (18·4 per cent) of the patients have also been interviewed 2 years after surgery. Thirty-one are free from reflux symptoms, two continue to experience dysphagia for some solid foods and 29 are satisfied with the clinical outcome.

Discussion

Laparoscopic Nissen fundoplication is being used increasingly in the treatment of gastro-oesophageal reflux disease. As with laparoscopic cholecystectomy, it has been adopted rapidly by many surgeons who have been encouraged by the short-term reports published in the surgical literature. This published experience also suggests, however, that laparoscopic fundoplication is associated with a significant learning curve[3,4,7]. The technical challenge resulting from the inherent difficulties of a three-dimensional environment reduced to two planes, and the requirement for suturing, has contributed to a steep learning curve. All previous reports have contained this learning component, suggesting the possibility that the outcome from surgery performed by surgeons who have overcome the learning difficulties of the procedure may be better than earlier reports have suggested.

This paper describes the outcome in a large number of patients who had laparoscopic fundoplication by surgeons who had each performed at least 20 procedures previously. While surgeons may progress at different rates, it is believed that 20 cases is a conservative estimate of the learning curve and that learning-related difficulties have been eliminated in this study. In comparison with the authors' earlier experience[4,5], and that of others[3,7], laparoscopic fundoplication by experienced surgeons is associated with an improved outcome. The median operating time of 80 min compares favourably with that in all publications reporting more than 50 procedures[3–7] (*Table 3*), in which median operating times ranged from 110 to 150 min.

The 5 per cent complication rate is an improvement on the rate of 10 per cent reported by this group previously[5] and of up to 13 per cent reported by others [3–7,11,15] (*Table 3*). Of importance was a reduction in the incidence of postoperative paraoesophageal herniation and venous thromboembolism in this group of patients. The unusual problem of hiatal stenosis was still seen in this adjusted series, although the necessity for revision of the fundoplication for persistent dysphagia was uncommon (two patients). The early reoperation rate of 2·3 per cent, as well as the overall reoperation rate, declined from the rate reported earlier[5]. Although the complication and reoperation rates compare favourably with previously published experience of open Nissen fundoplication[16–19], the early reoperation rate may be higher for the laparoscopic procedure. It is unusual for reoperation to be required within 12 months of open fundoplication. On the other hand, follow-up of patients who had laparoscopic fundoplication in this institution has been much more intensive because of the great interest in the outcome of this new technique. Importantly, this follow-up was obtained by a non-clinical scientific officer rather than the operating surgeon or any other member of the hospital clinical staff.

Late follow-up of 85 patients reviewed 12 months after surgery, and of 32 patients reviewed at 2 years, has confirmed the durability of laparoscopic fundoplication as a treatment for symptomatic gastro-oesophageal reflux; very few patients developed further reflux symptoms. The incidence of solid food dysphagia declined with longer follow-up, and patient satisfaction remained at 91 per cent 1 and 2 years after surgery.

Several important lessons were learnt during early experience with laparoscopic fundoplication, leading to changes in surgical technique; these, along with improved surgical experience, may have contributed to the improved outcome. Failure to repair the diaphragmatic hiatus adequately, as well as perforation of the left pleural membrane at laparoscopic fundoplication, resulted in a high incidence of early postoperative paraoesophageal herniation[9]. The introduction of routine hiatal repair and improved hiatal dissection protecting the pleura reduced the incidence of this complication, although the rate may still be higher than that during open surgery.

Greater experience has also reduced operating times considerably, despite the addition of short gastric vessel division in 35 per cent of patients, compared with very few patients in the authors' initial learning period. It should be noted, however, that short gastric vessel division was performed in the context of a randomized trial, rather than because of a definite change in practice.

Is laparoscopic fundoplication justified? Patient morbidity is greatly reduced by the procedure; most patients return home in 3 days, and are back at work by 2 weeks. However, when does the disadvantage of a small early reoperation rate balance the advantage of reduced pain and early discharge? Long-term outcome 5–10 years after laparoscopic surgery will need to be as good as that reported after open surgery. These outcomes will remain unclear for several more years and, until they are known, the procedure must remain under evaluation. Potential difficulties during the learning phase, when surgeons begin to perform laparoscopic antireflux surgery, can be minimized by the provision of expert supervision. The time is probably right for trials to compare the laparoscopic technique with open surgery.

Table 3 Early outcome following laparoscopic fundoplication

Reference	Year	No. of patients	Conversion rate (%)	Operating time (min)	Complication rate (%)	Follow-up (months)	Symptomatic failure (%)

The gastrointestinal tract is essential to host defence, acting as a barrier to absorption and translocation of gut antigens, including bacteria. In experimental models, protein malnutrition is permissive to gut barrier failure and endogenous infection. A clinical correlate has not been described. Intestinal morphology and barrier function to food protein antigens was studied in malnourished patients. Thirty-five individuals were evaluated, 20 malnourished patients and 15 well nourished hospital controls. Morphology was assessed from endoscopic biopsies of the second part of the duodenum, and serum immunoglobulin (Ig) G antibodies to gliadin and β-lactoglobulin were measured. No antibody to food proteins was evident in the control group. In contrast, serum IgG antibodies to at least one antigen were present in 15 malnourished patients and to both antigens in ten ($P < 0{\cdot}0001$ *versus* controls). Severely malnourished patients were more likely to have both antibodies present than those with mild or moderate malnutrition ($P < 0{\cdot}05$). Antibody-positive malnourished patients had significantly better nutritional status than antibody-negative patients with malnutrition ($P < 0{\cdot}05$). In no group of patients was there morphological evidence of abnormal mucosa or an immunological infiltrate. Gut barrier function is compromised in malnourished patients which suggests a mechanism that may facilitate gut-derived infection and sepsis.

The gastrointestinal mucosal barrier is central to host defence, excluding endogenous flora and toxins from the portal and systemic circulation. Failure of the gastrointestinal tract to act as an effective barrier may initiate or exacerbate sepsis in the surgical patient[1]. In the 'gut hypothesis' of sepsis and multiple organ failure, translocated enteric bacteria, in particular *Escherichia coli* and endotoxin, trigger widespread activation of pro-inflammatory cells with subsequent elaboration of cytokines which are the putative mediators of the metabolic, endocrine and neuroendocrine response[1]. The maintenance of gut barrier function is recognized as an important goal in the management of high-risk surgical patients and the critically ill[2,3]. The evidence from animal models is consistent but information on gut barrier function in relevant clinical situations is scant.

Malnutrition is prevalent in hospital patients and is associated with an enhanced risk of infection and sepsis[4,5]. The adverse effect of malnutrition on systemic immune function is well described[6–8]. Experimentally, malnutrition is associated with changes in the gastrointestinal tract, including intestinal weight loss out of proportion to weight loss in other viscera[9] and villus atrophy. The aims of this study were to determine whether malnourished patients have an altered immune response to dietary antigens, suggesting breakdown of normal antigen exclusion, and to assess the mucosa morphologically for signs of malnutrition, normally characterized by villus atrophy and absent brush borders[9].

Patients and methods

Ethical approval was obtained from the ethics committee of the Dublin Voluntary Hospitals. Thirty-five individuals were studied, 20 malnourished patients and 15 well nourished hospital controls. Protein malnutrition was defined by a score of 100 or less on the Nutrition Risk Index (NRI), calculated according to the following formula: 1·519 × serum albumin (g/l) + 0·417 × (current weight/usual weight) × 100. Malnutrition was further categorized as mild or borderline (NRI score 83·5–100) or severe (< 83·5) The methods used to develop these criteria have been described previously[10,11].

Following individual informed consent, endoscopic biopsies were obtained from the second part of the duodenum. All patients were feeding enterally before assessment, and none was avoiding wheat and milk. Patients receiving parenteral nutrition, those who had undergone operation, those with active peptic ulcer disease, inflammatory bowel disease, obstructive jaundice and acute pancreatitis, or on immunosuppressive medication, steroids and non-steroidal inflammatory drugs were excluded. Some 10 ml venous blood was taken and serum stored at −20°C for subsequent measurement of immunoglobulin (Ig) G antibodies to wheat (gliadin) and milk (β-lactoglobulin) protein.

Histopathology

Sections of small intestine were stained with haematoxylin and eosin. They were evaluated for villus height, crypt depth, villus area, brush border, lamina propria infiltrate and intraepithelial lymphocytes. The villus height was judged to be normal if the villus : crypt ratio was approximately 4 : 1. Ratios less than 3 : 1 were described as stubby. The number of intraepithelial lymphocytes per 300 epithelial cells was counted. Small intestinal morphology and immunocytochemistry were scored in a blinded fashion.

Detection of food antibodies to dietary protein

Enzyme-linked immunoabsorbent assays (ELISAs) for IgG antibodies to wheat and milk proteins were developed. Crude gliadin (Sigma Chemicals, Poole, UK) was dissolved in 0·1 ml acetic acid and β-lactoglobulin (Sigma) in carbonate–bicarbonate buffer. Microtitre plates coated with 100 μl of the antigen were stored overnight at 4°C, then washed four times with phosphate-buffered saline and 0·05 per cent Tween (PBS–Tween). Patients' sera and two reference sera (one positive and one negative) for each dietary antigen were added in 100 μl aliquots (in triplicate) at serial dilutions of 1/500, 1/1000 and 1/5000. Plates were incubated at 37°C for 40 min. The washing procedure was then repeated. Rabbit anti-human IgG conjugated with horseradish peroxidase diluted 1/1000 in PBS–Tween was applied at 100 μl

Paper accepted 30 November 1995

per well. Orthopheylene diamine in phosphate–citrate buffer 0·1mmol/l pH 5 containing hydrogen peroxide was used as substrate for the conjugate, applied at 100 μl throughout. The plates were covered with tin foil and left at room temperature. The colour reaction was stopped at 8 and 10 min using 50 μl sulphuric acid 2·5 mol/l, and was measured immediately with an automated spectrophotometer at 490 nm.

To ensure reproducibility of the ELISA, quality control serum samples of known content were included with each plate. Optical density values of test sera were read from the reference curve obtained by serial dilution of the reference serum for each dietary antigen. This standard curve was then used to estimate the antibody level (in arbitrary units) of each test sample.

Initially, sera from a control group of 22 healthy individuals were tested to establish a cut-off point; 95 per cent of this group had antibody levels of less than 1 arbitrary unit for both β-lactoglobulin and gliadin. A level of more than 1 arbitrary unit was thus selected as a cut-off point, with more than 1 arbitrary unit being considered positive.

Statistical analysis

Data were expressed as mean(s.e.m.). Non-parametric analysis was done using the Mann–Whitney *U* test. Categorical variables were analysed by Fisher's exact test.

Results

Fifteen of 20 malnourished patients had cancer (upper gastrointestinal (eight), colorectal (two), pancreatic (two), renal (two) and melanoma (one)), compared with seven of 15 (five upper gastrointestinal, two colorectal) in the well nourished control group (*P* not significant). The five malnourished patients without cancer had chronic pulmonary disease (three), stroke (one) and short bowel syndrome (one). Of the eight remaining patients in the control group, four had chronic pulmonary disease, two non-specific abdominal pain and two benign biliary disease. Median (range) age in the well nourished group was 58 (34–78) years compared with 64 (33–80) years in the malnourished group (*P* not significant). Mean(s.e.m.) NRI score in the malnourished group was 86(3) compared with 106(3) in the control group ($P < 0{\cdot}0001$). The corresponding mean(s.e.m.) albumin levels were 34(3) and 41(3) g/l ($P < 0{\cdot}0001$).

Serum IgG antibodies to gliadin or β-lactoglobulin were negative in all control patients. In contrast, antibodies to β-lactoglobulin were detected in 15 of 20 malnourished patients, to gliadin in ten, and both antibodies were found in ten ($P < 0{\cdot}0001$ *versus* controls for each parameter). Mean(s.e.m.) IgG level in antibody-positive patients was 2(0·5) arbitrary units for gliadin and 5·6(3) arbitrary units for β-lactoglobulin.

Gastrointestinal morphology was normal in both groups. One severely malnourished patient had stubby villi. In no patient was there evidence of brush border deficiency or goblet cell deficiency. There was no significant difference in mean(s.e.m.) intraepithelial lymphocyte infiltrates between malnourished (35(5) per 300 epithelial cells) and control (31(4) per 300 cells) groups.

Significance of antibodies to food antigens in malnourished patients

The significance of IgG antibodies to gliadin and β-lactoglobulin was further evaluated by comparing the 15 malnourished patients who were positive for antibodies with the five who were negative, and the ten patients who expressed both antibodies with the five who were positive for just one. Mean(s.e.m.) NRI score was 84(2) g/l and mean(s.e.m.) albumin level was 33(2) g/l in the antibody-positive group compared with 93(3) and 37(2) g/l respectively in the antibody-negative group ($P < 0{\cdot}05$). The respective values for patients with antibodies to both antigens were 82(3) and 33(3) g/l compared with 86(3) and 34(1) g/l for the five patients who were positive for one antibody (*P* not significant).

The presence of one or both antibodies strongly correlated with the degree of malnutrition. Within the malnourished group, ten patients had severe malnutrition, defined as an NRI score less than 83·5, and ten had mild or moderate malnutrition. In the severely malnourished group, nine patients expressed one antibody, eight both and one neither. In the mild to moderately malnourished group, six patients were positive for one antibody, two for both and four were antibody negative. Only the presence of both antibodies correlated with the severity of malnutrition ($P < 0{\cdot}02$ Fisher's exact test). Age, the presence of cancer and the site of disease were not significant factors. Five of seven malnourished patients without gastrointestinal disease had antibodies to food antigens, compared with ten of 13 with gastrointestinal disease. The situation was similar for patients without cancer; four of five such malnourished patients had antibodies for β-lactoglobulin.

Discussion

In animal models, protein malnutrition is associated with villus atrophy[9], abnormal intestinal mucin[12], reduced secretory (s) IgA[13], impaired effectiveness of oral vaccines[14] and absorption of whole protein[15]. In children with kwashiorkor, reduced levels and affinity of s-IgA have been reported[16], as well as reduced efficacy of oral vaccines and decreased intraepithelial lymphocytes[17]. Small intestinal morphology is altered and increased transport of the macromolecular antigen horseradish peroxidase has been observed in biopsy specimens from malnourished children[18]. The importance of the findings in this study is that they occurred in a prevalent group of hospital patients rather than at the extremes of malnutrition induced experimentally or observed in kwashiorkor.

Raised levels of IgGs to food antigens were observed in the absence of any morphological change in small intestinal mucosa. There are several possible underlying mechanisms, both immunological and non-immunological. The normal response to an oral antigen in immune homeostasis is termed tolerance: a state of non-reactivity protecting the host from intestinal damage by inappropriate immune activity, and characterized by local generation of harmless specific s-IgA and an absent hypersensitivity response to the same antigen in the systemic circulation. Evidence of a specific immune response to dietary antigens in the circulation is rare, occurring in less than 10 per cent of healthy individuals[19]. Impaired oral tolerance, classically seen in gluten-sensitive enteropathy (coeliac disease), is associated with raised levels of serum IgG to dietary protein. Over 90 per cent of untreated, newly diagnosed patients with coeliac disease in this department have values of more than 1 arbitrary unit for both β-lactoglobulin and gliadin antibodies. In contrast to the present morphological findings in malnourished patients, coeliac disease is characterized by immunologically-mediated intestinal injury, with villus atrophy and an immunological infiltrate of predominantly intraepithelial lymphocytes. Although local immunological mechanisms were not studied in detail, the absence of villus atrophy and intraepithelial lymphocyte infiltrate in patients with serum antibodies to food proteins suggests that impaired antigen-specific tolerance to dietary antigens is not a key mechanism in malnourished patients.

A non-antigen-specific break in tolerance that occurs as a consequence of defective intestinal barrier function may be more likely. In normal circumstances, up to 0·01 per cent of ingested dietary protein is absorbed in adults[20]. This is increased, and is associated with the presence of antibodies to food antigens in conditions causing increased gut permeability, such as Crohn's disease[21]. Although it is conceivable that antibodies to dietary proteins in malnourished patients are generated by the mucosal immune system in response to luminal antigen, perhaps indicating a secondary response to earlier sensitization, it is more likely that an immunologically significant quantity of intact protein or identifiable peptide fragments has been absorbed. Increased absorption may occur in the presence of normal histology either through defective tight junctions (paracellular) or altered transport mechanisms (transcellular). The latter possibility is consistent with observations by Heyman *et al.*[18] in jejunal biopsy material from severely malnourished infants. Their studies suggested that augmented transcellular absorption of the horseradish peroxidase resulted from decreased intracellular processing. Absent or impaired production of IgA may be relevant to this process[20]. This is supported by studies in patients with s-IgA deficiency, a primary humoral immunodeficiency that is estimated to occur in up to 1 in 400 people. There are many similarities between s-IgA deficiency and malnutrition, including increased incidence of antibodies to food and bacterial antigens, increased susceptibility to infection, and normal mucosal morphology. It is possible that in malnutrition, as in s-IgA deficiency, the presence of several antibodies to food antigens in the absence of local intestinal immunopathology suggests that the active mechanism of tolerance mediated by suppressor T cells is bypassed, with consequent generation of antibodies against multiple food antigens.

What are the clinical implications? The contribution of infection of gut origin to the high risk of septic morbidity and mortality in malnourished patients is not defined. Experimentally, bacterial translocation and mortality from sepsis is enhanced in malnourished animals challenged with proinflammatory stimuli[22,23]. Bacterial adherence to mucosal epithelial cells is also increased in experimental models of malnutrition[24]. Patients who receive total enteral nutrition (TEN) following major surgery or trauma have fewer septic complications than those receiving total parenteral nutrition (TPN)[25]. TEN, which nourishes the gut, prevents gastrointestinal mucosal atrophy, attenuates the injury stress response, maintains immunocompetence and preserves normal gut flora[26,27]. Although a comparison of the benefit of TEN *versus* TPN based on preoperative nutritional status has not been performed, the differences may be further magnified if the gut mucosa is malnourished from the outset. These data suggest a fundamental impairment in gut barrier function is present in malnourished patients. The presence of antibodies correlated with the degree of malnutrition suggesting that the barrier defect becomes more generalized to a variety of antigens with progressive malnutrition. There was no specific correlation with the presence of cancer or gastrointestinal disease, suggesting that it is malnutrition *per se* rather than the disease which causes the alteration in barrier function. It is possible, however, that once initiated, barrier breakdown may be a factor promoting further malnutrition. If the 'gut-origin' theory of sepsis is valid, a compromised gut barrier may initiate or amplify significant sequelae following major surgery or septic challenge which may provide the pro-inflammatory cytokines to further impair local defences and mediate adverse clinical events. Efforts to replete gut mucosa nutritionally to restore gut barrier function and prevent further impairment in the postoperative period merit evaluation in malnourished patients. Specific evaluation of glutamine is merited, since recent studies have shown that glutamine added to TPN may reduce intestinal permeability and decrease septic complications[28,29].

Non-randomized comparative trial of open (posterior) adrenalectomy *versus* laparoscopic adrenalectomy

N. E. Dudley and B. J. Harrison, *Departments of Surgery, John Radcliffe Hospital, Oxford and Northern General Hospital, Sheffield, UK*

Between 1991 and 1993, 23 adrenalectomies were attempted by one of the authors who had not previously undertaken the Hugh Young posterior approach.

Between 1993 and 1996, 15 laparoscopic adrenalectomies were attempted by both authors working synchronously. Comparative data are presented regarding conversion rate, inpatient hospital stay, operating time, blood loss, morbidity and mortality.

	Open (posterior)	Laparoscopic
Conversion rate	1 of 23	3 of 15
Mean (range) operating time (min)		
Unilateral	85 (60–110)	193 (120–270)
Bilateral	119 (80–155)	386 (360–435)
Blood loss*	2 of 22	1 of 12
Morbidity		
Wound infection	1 of 22	1 of 12
Chest infection	1 of 22	0 of 12
Prolonged ileus	1 of 22	0 of 12
Other	4 of 22	1 of 12 (port-site hernia)
Perioperative mortality	0 of 23	1 of 15 (cause unknown)
Mean (range) inpatient stay (days)		
Unilateral	8·2 (7–11)	3·0 (2–4)
Bilateral	8·7 (7–11)	3·8 (3·5–4)
Mean (range) age (years)	41·6 (24–62)	29·9 (5–75)

*Required transfusion of 2 units blood

Traditional *versus* laparoscopic surgery in the treatment of phaeochromocytoma: a preliminary study

P. Miccoli, C. Bendinelli, G. Materazzi, P. Iacconi and P. Buccianti, *Dipartimento di Chirurgia, Universita di Pisa, Italy*

The laparoscopic approach for removal of phaeochromocytoma has been questioned Six laparoscopic adrenalectomies for phaeochromocytoma have been performed recently and the results are compared with those obtained using traditional open surgery

Between January 1988 and April 1995, 26 patients underwent surgery for phaeochromocytoma: 20 had an adrenalectomy through an upper abdominal transverse incision (group 1), and five unilateral and one bilateral laparoscopic adrenalectomy (group 2). There were 11 women in the first group and one in the second. Mean(s.d.) diameter of the mass was 5·8(5·8) and 5·3(2·1) cm respectively In both groups the right adrenal was affected twice as often as the left.

The following parameters were studied: operating time, hypertensive intraoperative crises, estimated blood loss, volume of liquid infused, day on which patients were back to semiliquid and full diets, complications and day of discharge. Mean follow-up was 56 months in group 1 and 10 months in group 2.

Mean operating times were 142 and 182 min in groups 1 and 2 respectively. In both groups, blood loss was similar: mean(s.d.) 311(40) ml in group 1 and 342(23) ml in group 2. Postoperative liquid infused was 9·6 litres in patients who had open surgery and 5·9 litres in those operated on with the laparoscopic approach, the largest difference in the liquid infused was observed after the first 24 h.

Patients operated on laparoscopically were discharged 3 days earlier In group 1 four patients developed fever and in two cases an infected wound was observed; one of them evolved into superficial dehiscence. The mean time elapsed to resume normal activity and return to work was reduced by 1 month in patients who underwent laparoscopic adrenalectomy.

Laparoscopic adrenalectomy: technical aspects based on a primary vascular dissection

J. Marescaux, D. Mutter and M. H. Wheeler*, *European Institute of Telesurgery (IRCAD-EITS) and University Department of Digestive and Endocrine Surgery, Hôpital Civil, Strasbourg, France and *Department of Surgery, University Hospital of Wales, Cardiff, UK*

This experience is based on 29 patients and observation of the technique of several pioneers (M. Gagner, L. Fernandez-Cruz, P. Miccoli). A technique using primitive vascular dissection ensures better adrenal and periglandular fat removal. The surgical procedure used a full lateral-decubitus and transperitoneal flank approach.

The key to successful left adrenalectomy is to start the procedure by dissecting the splenoparietal ligament close to the diaphragm to permit complete mobilization of the spleen to the right with the tail of the pancreas. Dissection of 5 cm of the splenic vein, used as a landmark, permits exposure of the renal vein which leads to the main and accessory adrenal veins. They can be divided safely between clips. The right side of the gland is dissected up to the diaphragm with clipping of the middle and upper arterial pedicles. Adrenalectomy is achieved by simple dissection of the fat. The gland is extracted though a bag.

The fundamental step of the right adrenalectomy procedure is sectioning of the hepatoparietal ligament far to the right allowing upward mobilization of the liver. The second step consists of dissecting towards the vena cava using this structure as a landmark to find the renal vein, which is the inferior limit of the dissection. The main adrenal vein is doubly clipped and divided. The third step is to look for an accessory adrenal vein joining a subhepatic vein above the main adrenal vein. The adrenal arteries are dissected on the right side of the vena cava. The last step is straightforward coagulation, vessel clipping and division, as on the left side

Indications for a laparoscopic approach in adrenal surgery

J. F. Henry, A. Denizot and M. Puccini, *Department of Endocrine Surgery, CHU la Timone, Marseille, France*

It has been demonstrated that the laparoscopic approach can be used safely and successfully in adrenal surgery. The aim of this study was to determine the indications for the laparoscopic approach in adrenal surgery.

Between June 1994 and November 1995, 56 patients underwent adrenalectomy for Conn's syndrome (23), Cushing's syndrome (ten), phaeochromocytoma (12), adrenocortical carcinoma (three) and incidentaloma (eight). A laparoscopic transabdominal flank approach was proposed in patients presenting with solitary or unilateral tumours measuring less than 8 cm in diameter, without suspicion of malignancy and without the usual contraindications to laparoscopic surgery.

Laparoscopic adrenalectomy was performed in 36 patients (64 per cent), with Conn's syndrome (20), Cushing's syndrome (eight), phaeochromocytoma (five) and incidentaloma (three). Mean size of the tumour was 26 (range 7–75) mm. Malignancy was demonstrated in two tumours. Four of 36 patients required laparotomy because of inadequate dissection (three) or operative suspicion of malignancy (one). Mean operating time was 159 (range 75–300) min. There were no deaths.

Postoperative complications were: bleeding from a trocar site (one), spleen infarction (one) and phlebitis (one). All patients with functioning tumours are disease free. The other 20 patients underwent open adrenalectomy. The laparoscopic approach was not recommended because of suspicion of malignancy (nine), previous surgery (seven), or bilateral or multiple tumours (four).

The laparoscopic approach is the procedure of choice in patients with functioning adenoma and sporadic unilateral intra-adrenal phaeochromocytoma. It may be discussed in patients with familial phaeochromocytoma. It is not indicated in patients with large (greater than 8–10 cm) or malignant tumours.

Benefits of routine laparotomy as the surgical approach for phaeochromocytoma and abdominal paraganglioma

C. A. G. Proye, F. N. Pattou, F. P. Combernale, B. Carnaille, X. Marchandise, M. Steinling, D. Huglo and C. L'Hermine, *Service de Chirurgie Generale et Endocrinienne, Centre Hospitalier Universitaire de Lille, Lille, France*

The records were studied of 100 patients who had undergone abdominal exploration and resection of at least one intra-abdominal phaeochromocytoma or paraganglioma over the past 17 years. Tumours were benign in 81 patients and malignant in 19 (nine locally invasive, seven with positive node(s), six with distant metastases), intra-adrenal in 83 patients (bilateral in 13) and extra-adrenal in 17, sporadic in 72 patients, and occurring in a genetic setting in 28. Abdominal (and possibly pelvic) computed tomography (CT), ^{131}I-*m*-iodobenzylguanidine (MIBG) scintigraphy and magnetic resonance imaging (MRI) had been performed since 1979, 1984 and 1987 in 97, 73 and 43 patients respectively. False-positive and false-negative results had been defined as any discrepancy between imaging result and surgical findings.

Imaging	*n*	False-positive (%)	False-negative (%)
CT	97	4	11
MIBG scintigraphy	73	7	16
MRI	43	5	9

Most of the inaccurate results were related to the localization of the tumour (either intra- or juxta-adrenal) or to the extent of periadrenal invasion. CT overlooked only two minute tumours in a familial setting of multicentric disease. MRI overlooked four tumours, including the two overlooked by CT. A striking feature was that all false-positive results of MIBG scintigraphy occurred in a genetic setting (four) or in teenagers (one). When the three techniques were combined in 38 patients, only one tumour, occurring in a bilateral and genetic setting, was overlooked.

The improved accuracy of available imaging techniques questions the strategy of routine laparotomy for sporadic phaeochromocytoma, favouring approaches such as the posterior or laparoscopic technique.

Clinical spectrum and outcome of functional extra-adrenal paraganglioma

D. S. O'Riordain, C. S. Grant, J. A. Carney and J. A. van Heerden, *Department of Surgery, Mayo Clinic and Foundation, Rochester, Minnesota, USA*

Functioning extra-adrenal paragangliomas represent over 10 per cent of all phaeochromocytomas, occur at diverse anatomical locations and are said to have a higher malignancy rate than intra-adrenal phaeochromocytomas.

Sixty-six patients had surgery for catecholamine-producing paraganglioma between 1952 and 1992. Median follow-up was 8·8 years. Median age was 40 (range 11–67) years; there were 29 men. Familial disease occurred in nine (14 per cent), and ten patients (15 per cent) also developed adrenal phaeochromocytoma.

Solitary paragangliomas occurred in 52 patients: 46 abdominal, four thoracic and two of the head and neck. Fifty-three tumours developed in 14 patients with multiple paragangliomas: 38 abdominal and 15 thoracic. Of 28 patients with solitary tumours undergoing localization studies in the past 10 years, accurate localization was achieved in 27. There was one operative death, 15 patients had persistent disease and 50 were cured. Of those cured, nine developed recurrence; disease-free survival rate was 86, 80 and 80 per cent at 5, 10 and 20 years respectively. Fourteen patients (21 per cent) had metastatic disease, of whom seven have died. An additional ten patients (15 per cent) had locally invasive disease, of whom four have died. Cause-specific survival rate at 5, 10 and 20 years was 90, 83 and 72 per cent respectively. Risk factors for death from phaeochromocytoma were tumour size greater than 5 cm ($P = 0{\cdot}0002$), metastatic disease ($P = 0{\cdot}001$) and tumour invasion ($P = 0{\cdot}002$). Cause-specific survival rate for patients with tumours greater than 5 cm was 59 per cent at 15 years compared with 100 per cent for those with tumours of 5 cm or less ($P = 0{\cdot}0003$).

Functional paragangliomas are frequently malignant and are associated with a high incidence of persistent or recurrent disease. Tumour size above 5 cm and the occurrence of invasive or metastatic disease are strong predictors of outcome. The majority of tumours are abdominal and imaging is highly successful in localization

Adrenalectomy in the treatment of Cushing's syndrome

S. Kocak, S. Ozbas, S. Aydrntug, S. Baskan and S. Eraslan, *Department of Surgery, Ankara University Medical School, Ankara, Turkey*

Trans-sphenoidal pituitary microsurgery is the treatment of choice in Cushing's disease but this treatment is not successful in all patients.

Between 1990 and 1995 nine patients with adrenocortical adenoma and 18 with bilateral adrenal hyperplasia were treated by adrenalectomy. All had complete symptomatic relief and there was no operative mortality or serious morbidity. Adrenalectomy should be the treatment of choice in patients with adrenocortical adenoma, and patients with Cushing's disease should be treated with bilateral adrenalectomy when pituitary surgery fails or cannot be performed.

Seven patients in this series had previously undergone trans-sphenoidal pituitary microsurgery; autonomous secretion of cortisol by the adrenocortical nodules was the cause of persistent disease in patients with nodular hyperplasia. Nodular adrenocortical hyperplasia may be a cause of persisting Cushing's syndrome following successful trans-sphenoidal pituitary surgery.

Adrenal autotransplantation may be carried out in patients with bilateral adrenalectomy to avoid lifelong replacement of steroids. The transplanted adrenal tissue should be stimulated by a cortisone-weaning process and autograft function should be determined by radioisotope scanning, not by hormone measurement.

Surgical strategy for organic hyperinsulinism

D. Simon, P. E. Goretzki and H.-D. Roher, *Department of Surgery, Heinrich Heine University, Dusseldorf, Germany*

Organic hyperinsulinism may be due to solitary or multifocal lesions, hereditary disease/multiple endocrine neoplasia (MEN) I, diffuse hyperplasia or malignancy. Precise biochemical diagnosis, standardized surgical exploration and consideration of distinctive features are essential for a successful surgical outcome. The necessity for preoperative and intraoperative localization techniques and management of multifocality and malignancy in organic hyperinsulinism remain controversial issues.

Between April 1986 and January 1996, 50 patients presented with organic hyperinsulinism. Forty patients had solitary adenomas, three multiple adenomas, two MEN I syndrome, one diffuse hyperplasia and four malignant insulinomas. Four patients underwent reoperation for recurrent disease (three with multiple adenomas, one with MEN I). Preoperative localization included abdominal ultrasonography, computed tomography, magnetic resonance imaging, endoscopic ultrasonography, angiography, octreotide scintigraphy and venous sampling. Preoperative localization was known and correct in 50 per cent of patients At operation, five tumours were not palpable; four of these could be detected by intraoperative ultrasonography. Mean size of the tumour was 16 (range 3–60) mm. Enucleation was performed in 28 patients (56 per cent), resection in 17 (34 per cent) (left resection 12, Whipple three, subtotal two), combined procedures in four (8 per cent) and hepatic resection in one patient.

Euglycaemia was achieved in 47 patients, including one with a two-stage operation after diagnosis of nesidioblastosis. All four patients with recurrence of disease had euglycaemia (three had multiple tumours and one MEN I; two underwent multiple enucleation and two resection) Three patients with malignant disease showed considerable improvement of symptoms. Two of these patients with symptomatic liver metastases were treated additionally by chemotherapy or chemoembolization.

It is concluded that (1) preoperative localization techniques do not influence surgical outcome and can be omitted; (2) intraoperative ultrasonography is indispensable for detection of small or multiple tumours; (3) patients with multiple tumours run a high risk of recurrence and so meticulous exploration with adequate resection or multiple enucleation is required; and (4) in malignant disease, radical removal of the primary lesion or tumour debulking can achieve relief from symptoms and potential cure

Laparoscopic treatment of insulinoma and gastrinoma

E. Cavina, P. Miccoli, P. Buccianti, P. Iacconi, O. Goletti, M. Chiarugi and M. Conte, *Dipartimento di Chirurgia, Universita degli Studi di Pisa, Italy*

This report describes two patients with pancreatic endocrine tumours successfully treated laparoscopically: a 23-year-old man with Zollinger–Ellison syndrome and a 47-year-old woman with an insulinoma. A precise biochemical diagnosis had been made and localization studies had determined the site of the tumours in the upper edge of the pancreas.

Patients underwent a traditional laparoscopic approach using four trocars in the first and five trocars in the second patient. Intraoperative ultrasonography was carried out to study the liver and pancreas through the stomach wall (7·5-MHz probe with flexible tip). In the first patient, a 2·2-cm extrapancreatic nodule contiguous to the upper border of the pancreas was visible through the lesser omentum; the echographic study was completed by endoscopic sonography of the pancreatic head and duodenum which confirmed the presence of a solitary nodule with no evidence of liver and lymph node metastases. In the second patient, a 2-cm tumour under the pancreatic body capsule was identified by intraoperative ultrasonography. Both tumours were resected, the second being enucleated from the pancreas by electrocautery and endoclips. Serum insulin and gastrin levels decreased after operation, confirming the radicality of the laparoscopic removal of the neoplasms. The patients were discharged after 2 and 4 days of an uneventful postoperative course.

Laparoscopic exploration and intraoperative ultrasonography might represent the first step in the surgical management of patients presenting with islet cell tumours.

Cytokines and neural cell adhesion molecule/CD 56 in the interaction between neuroendocrine tumours and natural killer cells

B. Wangberg, O. Nilsson, K. Hellstrand, G. Westberg and H. Ahlman, *Departments of Surgery, Pathology and Clinical Virology, Sahlgrenska University Hospital, Goteborg, Sweden*

Neural cell adhesion molecule (NCAM), or 56 DC, mediates both homophilic cell–cell interactions and heterophilic cell–matrix interactions Natural killer (NK) cells express CD 56 and are a subset of lymphocytes that kill tumour cells in a non-major histocompatibility complex-restricted fashion.

The occurrence of NCAM/CD 56 in neuroendocrine tumours was analysed by immunocytochemistry and Western blot analysis using the monoclonal antibody ERIC-1, which detects all four isoforms of NCAM/CD 56. Western blot analysis demonstrated a major 140-kDa band in foregut carcinoids (three of three), midgut carcinoids (14 of 15), islet cell tumours (four of four), phaeochromocytomas (ten of ten) and medullary thyroid carcinomas (five of five). Immunolabelling was confined to cell membranes of tumour cells, with no labelling over cytoplasm or nuclei. Primary cultures of midgut carcinoids (six of eight) also showed the strongest labelling at cell–cell contacts. NCAM/CD 56 could not be detected in any of 15 colonic cancers.

During embolization of carcinoid liver metastases, pronounced activation of the NK cell system occurs in patients with good clinical response, probably as a result of the release of tumour cell products (serotonin, cytokines) during ischaemia. The cytotoxic activity of NK cells exerted on such tumours in primary cell culture ($n=5$) could be enhanced by incubation with exogenous interleukin 2 (4–20-fold) or interferon α (3–14-fold).

NCAM/CD 56 was demonstrated in the majority of neuroendocrine tumours and may be important in the interaction between these tumour cells and the host immune system, possible enhancing NK cell antitumour activity together with cytokines.

Clinical localization of parathyroid glands using [^{11}C]methionine position emission tomography scans for repeat exploration parathyroidectomy

W. J. B. Smellie, G. J. R. Cook, I. Fogelman, M. N. Maisey and A. E. Young, *UMDS of Guy's and St Thomas's Hospitals, Clinical PET Centre and Directorate of Surgery, London, UK*

Preoperative assessment of the anatomical location of parathyroid glands is an advantage in patients who have persistent hypercalcaemia after neck exploration for hyperparathyroidism to assess whether the glands are in an abnormal position and to guide dissection in heavily scarred necks.

Fifteen patients with primary and five with tertiary hyperparathyroidism with between one and three previous surgical explorations were included. All [^{11}C]methionine position emission tomography (PET) scans were compared with technetium-99m MIBI ($n=16$) or thallium-201 ($n=4$) parathyroid scans. Surgery was subsequently performed in seven patients. Scans of the neck and mediastinum were obtained 15 min after administration of 370–540 MBq [^{11}C]methionine. A further ten patients without previous surgery were also studied.

In patients with previous surgery, scans showed an abnormality in 11 of 15 with primary hyperparathyroidism and in two of five with tertiary hyperparathyroidism. Corresponding technetium-99m MIBI scans were abnormal in three of 15 and two of five. In the four patients operated on for primary hyperparathyroidism, all four glands were correctly localized by PET. In the three patients operated on for tertiary hyperparathyroidism two of three glands were subsequently shown by surgery to have been correctly localized by PET. In one patient technetium-99m MIBI correctly localized the glands but PET did not.

In the eleven patients without previous operations, PET localized the glands correctly in seven of eight patients with primary hyperparathyroidism and in three of three with tertiary hyperparathryroidism. Technetium-99m MIBI correctly localized four of eight and one of three.

[^{11}C]methionine PET may offer an alternative method of preoperative localization in patients with hyperparathyroidism. Preoperative localization is not necessary in patients initially diagnosed with hyperparathyroidism but [^{11}C]methionine PET may be more sensitive in localizing glands in patients in whom previous surgery has been performed.

Sestamibi–technetium subtraction scintigraphy in primary hyperparathyroidism

S. E. Refsum, J. D. Laird, W. R. Ferguson and C. F. J. Russell, *Departments of Endocrine Surgery and Nuclear Medicine, Royal Victoria Hospital, Belfast, UK*

Successful preoperative localization of parathyroid adenomas by subtraction scintigraphy has been limited by the inability of thallium–technetium scanning to identify small tumours. With a view to improving the sensitivity of the investigation, the isotope sestamibi has been substituted for thallium and, since January 1993, sestamibi–technetium subtraction scintigraphy has been performed routinely in patients with proven primary hyperparathyroidism (HPT) before neck exploration.

Between 1 January 1993 and 31 July 1995, 67 patients had sestamibi scans before first-time cervical exploration for HPT. Five scans were technically unsatisfactory and records could not be retrieved for eight patients. Of the remaining 54 individuals, 44 had a positive scan (one focus of activity after subtraction) and ten scans were negative. At operation, 48 patients each had a solitary adenoma, four had multigland enlargement and one had a parathyroid carcinoma.

For 48 patients with adenoma the scan result was correlated with operative findings and tumour weight:

	Weight of adenoma		
	<0·5 g	0·5–1·0 g	>1·0 g
Scan result			
True positive	11 (69)	9 (75)	18 (95)
False positive	5 (31)	3 (25)	1 (5)

Values in parentheses are percentages. One adenoma was not weighed

Sensitivity of the scan for detecting solitary parathyroid adenoma was 81 per cent; false-negative rate was 19 per cent. Sestamibi–technetium subtraction scintigraphy successfully localizes a high proportion of adenomas in HPT.

Tetrofosmin–^{123}I subtraction scanning in preoperative parathyroid imaging

C. A. G. Proye, B. Carnaille, C. P. Oudar, M. Steinling, M. Lecomte and D. Huglo, *Service de Chirurgie Generale et Endocrinienne, Centre Hospitalier Universitaire de Lille, Lille, France*

Tetrofosmine (TTF) is a cardiac imaging agent that may serve as a new radiopharmaceutical for parathyroid scanning before surgical exploration in patients with primary hyperparathyroidism (HPT).

Forty-six patients with primary HPT had a TTF–^{123}I scan followed by bilateral surgical neck exploration; all enlarged glands were excised, regardless of scan results. For TTF–^{123}I parathyroid scanning, planar images of the neck and mediastinum were performed 20 min and 2 h after injection of 15 milliCi (555 MBq) TTF (1,2-bis[bis(2-ethoxyethyl)phosphoro] ethane; Myoview, Ametstam Laboratory). Then, 150 μCi (5·5 MBq) ^{123}I was injected. Planar images were performed 2 h afterwards and subtracted from TTF images.

Eucalcaemia was achieved in all patients after operation. During surgery, 174 parathyroid glands were identified including 58 enlarged ones (31 adenomas and 27 hyperplastic). HPT was uniglandular in 36 patients and multiglandular in ten. TTF–^{123}I scanning correctly detected 44 enlarged glands (sensitivity 76 per cent, specificity 100 per cent) weighing 70–17 000 mg but overlooked 14 enlarged glands (four adenomas and ten hyperplastic) weighing 50–638 mg. Among the overlooked glands, four weighed more than 100 mg. Among 36 patients with uniglandular disease only two scans were falsely negative, whereas among ten patients with multiglandular disease all enlarged glands were successfully imaged in two patients only. One of four mediastinal adenomas was overlooked. TTF–^{123}I scanning results were not significantly correlated with preoperative 1–84 parathyroid hormone levels.

TTF–^{123}I subtraction scanning is one more improvement in preoperative imaging of the parathyroid glands, occasionally detecting hyperplastic glands as small as 70 mg. It does not allow successful imaging of all enlarged glands in multiglandular disease and can overlook tiny mediastinal adenomas.

Health screening for primary hyperparathyroidism with serum calcium and parathyroid hormone values in menopausal women

E. Lundgren, J. Rastad, G. Akerstrom and S. Ljunghall*, *Departments of Surgery and *Internal Medicine, University Hospital, Uppsala, Sweden*

Primary hyperparathyroidism (HPT) was screened for during mammographic health control of 5202 women aged 55–75 years. Re-examination of individuals with a serum calcium level of 2·55 mmol l^{-1} or more substantiated primary HPT in 2·1 per cent of the population. Primary HPT was diagnosed in women lacking substantial renal impairment, lacking a family history of hypercalcaemia, and low urinary calcium excretion providing the presence of hypercalcaemia and intact serum parathyroid hormone (PTH) 25 ng l^{-1} or more (37 women), serum calcium 2·50–2·60 mmol l^{-1} and serum PTH 35 ng l^{-1} or more (55 women), or serum calcium below 2·50 mmol l^{-1} and serum PTH above the normal range (17 women). Serum calcium and PTH values were 2·32–3·19 (mean 2·59) mmol l^{-1} and 34–300 (mean 66·5) ng l^{-1} respectively. These values were positively correlated ($P=0·0001$) and were significantly higher ($P<0·0001$) than those in matched controls. Thirty patients demonstrated persistent normocalcaemia; all but two of them also showed consistently normal ionized plasma calcium concentrations. Within a stratified treatment programme, 60 of the patients have undergone parathyroid surgery with removal of pathological parathyroid tissue. This attempt systematically to explore and to verify diagnostic levels of serum PTH at operation in population-based health screening substantiates the considerable prevalence of primary HPT in menopausal women and suggests that criteria used for biochemical recognition may underdiagnose the disorder

Near-patient measurement of intact parathyroid hormone during parathyroidectomy

C. R. Squire, P. M. Hawksworth, S. V. Fox, P. Atkins* and W. D. Fraser, *Departments of Clinical Chemistry and *Surgery, Royal Liverpool University Hospital, Liverpool, UK*

Parathyroidectomy for parathyroid adenoma can be a difficult operation, especially if there has been previous surgery. Localization and confirmation of successful surgical removal of the adenoma can be assisted by parathyroid hormone (PTH) measurement in venous samples taken from the drainage area of the four glands, provided that timely results can be obtained.

A modified protocol for the Nichols Institute (Essex, UK) chemiluminometric assay for intact PTH was used and carried out in the theatre suite. Samples were collected into tubes containing ethylenediamine tetra-acetic acid and centrifuged at 13 000 r p.m. for 30 s in a microcentrifuge. The assay was carried out in duplicate according to the manufacturer's instructions except that samples were incubated for 10 min in a rotary incubating block at 50°C. A previously stored standard curve was used with two calibrators and two quality-control samples.

The time taken from receipt of the samples from theatre to reporting the results varied between 20 and 27 min, depending on the number of samples analysed

Intrabatch coefficient of variation was 10·5 per cent at 2·3 pmol l^{-1} and 5·8 per cent at 37·7 pmol l^{-1}. Interbatch coefficient of variation was 18·1 per cent at 3 7 pmol l^{-1} and 9·7 per cent at 18·1 pmol l^{-1}. Correlation between the rapid assay and routine immunoradiometric assay (Nichols Institute Intact PTH) was $y = 0\ 9x + 1\ 8$, $r = 9{\cdot}98$.

Using this method the location of an adenoma has been correctly identified and confirmed at successful removal in six patients.

Clinical and physiological responses to total parathyroidectomy after renal transplantation

T. J. Wheatley, T. M. Doughman, P. S. Veitch and M. L. Nicholson, *Department of Surgery, Leicester General Hospital, Leicester, UK*

Despite improvements in the medical management of secondary hyperparathyroidism, parathyroidectomy is still necessary in some renal transplant recipients. The operative strategy in this situation remains controversial Total parathyroidectomy has been criticized because of concern that the aparathyroid state will lead to adynamic bone disease and difficulties in therapeutic management

Total parathyroidectomy was carried out in a group of 21 patients with renal transplants. Total parathyroidectomy was performed in the 5-year period before renal transplantation (15 patients) or between 6 and 33 months after transplantation (six). Indications for surgery were severe bone disease (11 patients), uncontrolled hypercalcaemia (tertiary disease) (six), soft tissue calcification (one) and grossly raised parathyroid hormone (PTH) level (three). Surgery consisted of four-gland parathyroidectomy and included transcervical thymectomy where necessary.

The clinical and biochemical success rates at 24 months' follow-up were 87 and 100 per cent respectively Detailed skeletal surveys demonstrated evidence of partial or complete bone healing in 93 per cent of patients followed to 2 years. Postoperative PTH levels (measured by a sensitive immunoradiometric assay) demonstrated residual parathyroid function in 17 of 21 patients. At 2 years' follow-up there was only one patient with recurrent hypercalcaemia. Postoperative intravenous calcium infusion was necessary in 12 patients. Vitamin D analogues were required in 17. There was no recurrent laryngeal nerve palsy or permanent voice change after surgery. There has been no clinical evidence of adynamic bone disease and no therapeutic difficulty in any patient.

The data presented suggest that total parathyroidectomy is a safe and effective procedure in patients on dialysis who are awaiting a kidney transplant or in renal transplant recipients.

Fibroblast growth factors and receptor expression in proliferative disorders of the parathyroid

C. L. Eaton, D. L. Lambert and B. J. Harrison, *Department of Surgical Sciences, Clinical Sciences Centre, Northern General Hospital, Sheffield, UK*

The activities of polypeptide growth factors are important in the control of proliferation in glandular tissues. Previous studies have reported the presence of growth factors in abnormal parathyroid tissue. A basic fibroblast growth factor (FGF)-like factor is reported to be a potent mitogen for parathyroid tissue and may be implicated in the parathyroid disorder multiple endocrine neoplasia I.

The expression of acidic and basic FGFs and of FGF receptor (FGR-R) types 1 and 2 has been studied in human parathyroid tissue, utilizing Northern blot and reverse transcription–polymerase chain reaction (PCR) methodologies. To date RNA from seven adenomatous and 11 renal hyperplastic glands has been isolated. Comparison of the samples examined using primer pairs covering an extracellular domain of FGF-R types 1 and 2 has demonstrated the presence of transcripts for these genes in all samples. No gross difference in either PCR-amplified fragment size or level of expression was observed between glands from patients with primary and renal hyperparathyroidism. Detailed sequence analysis of PCR products and consideration of other primer pairs covering sequences encoding different functional domains of these receptors is currently ongoing.

Kindred with familial medullary thyroid carcinoma: expression of medullary thyroid carcinoma in heterozygous and homozygous disease gene carriers

C. Franz, J. Rice, H. Donis-Keller and S. A. Wells Jr (introduced by C. Proye), *Department of Surgery, University of Hamburg, Hamburg, Germany and Departments of Genetics, Psychiatry and Surgery, Washington University School of Medicine, St Louis, Missouri, USA, (Service de Chirurgie Generale et Endocrinienne, Centre Hospitalier Universitaire de Lille, Lille, France)*

Germline mutations in the *RET* proto-oncogene are associated with multiple endocrine neoplasia type 2 and familial medullary thyroid carcinoma (MTC). In a familial MTC kindred a novel point mutation in *RET* (codon 804 Val to Met) was identified and several individuals were homozygous for this mutation.

The expression of MTC in homozygous and heterozygous disease gene carriers was compared. Mutation analysis of 74 family members revealed 47 (16 homozygous and 31 heterozygous) disease gene carriers and 27 non-carriers. Ten of 31 heterozygous carriers and 15 of 16 homozygous carriers had disease. In unaffected carriers median age was 38 (range 24–69) years. Using survival analysis technique, age at diagnosis was significantly earlier in homozygous carriers ($P = 0{\cdot}002$, Wilcoxon test). Median age in the homozygous and heterozygous carriers was 49 and 60 years respectively. Preoperative stimulated calcitonin levels were higher in homozygous carriers, and lymph node metastasis (four individuals), persistent disease (three) and recurrent (two) disease occurred only in homozygous carriers. Expression of MTC is more apparent in homozygous disease gene carriers.

Medullary thyroid carcinoma in Northern Ireland

S. J. Dolan and C. F. J. Russell, *Department of Endocrine Surgery, Royal Victoria Hospital, Belfast, UK*

Medullary thyroid carcinoma (MTC) remains a rare malignancy. Between 1960 and 1995, 33 patients with MTC were treated at this hospital. Twenty-one patients had sporadic tumour; the remaining 12 had MTC as one component of multiple endocrine neoplasia (MEN) type 2A (ten patients) or type 2B (two) syndrome. All 33 individuals had histologically proven invasive carcinoma. Twelve patients (ten with sporadic tumour, two with MEN) had undergone thyroidectomy at other hospitals, although none had had total thyroidectomy.

Median age at presentation was 40·5 years for patients with sporadic tumour and 28·5 years for patients with MEN 2A. Clinically, 20 of the former patients and seven of those with MEN 2A had palpable goitres while ten and one respectively had cervical lymphadenopathy. One patient with MEN 2A had raised plasma calcitonin levels in the absence of clinical disease. Recently, a 10-year-old girl with MEN 2A underwent total thyroidectomy on the basis of positive genetic information alone.

Crude 5-year survival rate was 30 per cent for patients with sporadic MTC and 60 per cent for the MEN 2A group. Of the patients with sporadic tumour, 17 or 21 are dead (mean survival 61·2 months); seven of the ten patients with MEN 2A remain alive between 1 and 16 years (mean 104 months) after operation.

Improved survival in the MEN 2A setting may reflect a combination of biological behaviour of tumour, earlier diagnosis, less advanced disease and appropriate radical surgery.

Early diagnosis of sporadic medullary thyroid carcinoma by routine measurement of serum calcitonin levels

M. Puccini, P. Miccoli, A. Denizot, C. de Micco, B. Conte-Devolx and J. F. Henry, *Department of Endocrine Surgery, CHU la Timone, Marseille, France*

Sporadic medullary thyroid carcinoma (MTC) has a significant associated mortality rate. The 10-year survival rate is around 60 per cent. It may be expected that diagnosis and treatment at an early stage will improve prognosis This study assessed the diagnostic accuracy of serum calcitonin (CT) measurement in detecting sporadic MTC in patients with thyroid disease.

Between 1993 and 1995, 2974 patients presenting with thyroid disease had basal CT measurement (Elsa-h CT kit, CIS-Bio industries, normal level less than 10 pg ml^{-1}). When serum basal CT level was above the normal range, a pentagastrin stimulation test was performed (normal value less than 30 pg ml^{-1}). Sporadic MTC was suspected in patients with a CT peak above 100 pg ml^{-1}. Clinical solitary or dominant nodules were assessed by fine-needle aspiration cytology (FNAC). No patient had a history of familial MTC or multiple endocrine neoplasia II.

In 13 patients (0·4 per cent) sporadic MTC was diagnosed. In eight patients (group 1) diagnosis was made both by FNAC and CT measurement but in five patients initial cytological diagnosis was incorrect: anaplastic (two), papillary (two), benign (one). A revised cytological diagnosis of sporadic MTC was made after detecting raised serum CT concentration. In the last five patients (group 2) sporadic MTC was not detected clinically and FNAC was not performed. Sporadic MTC was diagnosed before operation by raised serum CT level alone. In this group mean size of the tumour was 6 (range 1·2–9) mm and there was no lymph node involvement. After surgery, only four of the eight patients in group 1, but all five patients in group 2, had a normal CT concentration.

Routine measurement of serum CT improves the preoperative diagnosis of sporadic MTC and allows early diagnosis of occult tumours.

Familial papillary carcinoma of the thyroid

J.-L. Kraimps, R. Marechaud and J. Barbier (introduced by C. Russell and B. Carnaille), *Department of Surgery, Jean Bernard Hospital, Poitiers, France*

Papillary thyroid carcinoma (PTC) is usually sporadic but may be familial. The relative frequency of familial *versus* sporadic papillary carcinoma is uncertain. Autosomal dominant inheritance with incomplete penetrance is possible. This study examined 15 patients with familial PTC and attempted to define a diagnostic and therapeutic approach.

During the past 5 years, familial occurrence of PTC was observed in 11 patients from seven families. Questioning these patients revealed four other individuals with PTC in their family. Where familial occurrence was indicated by the patient, attempts were made to obtain pathology reports to confirm the diagnosis. A complete pedigree was obtained. Statistical analysis was based on corrected χ^2 test with Yates' correction.

Within these seven families, 28 patients had a nodular goitre and 24 underwent surgery. Nine had a multinodular goitre and 15 had PTC. During the same time, 105 patients with PTC were operated on, with a 10·5 per cent rate of familial PTC. There were ten women and five men, with two affected relatives in six families and three in one family. Mean age was 33 (range 11–66) years. The relationship between patients was 'parent and child' in three families, 'siblings' in two families and 'cousin' in two families. PTC was multifocal in seven of 15 patients *versus* 22 (23 per cent) of 94 patients with sporadic PTC treated in the same time. This difference, however, was not significant.

It can be concluded that (1) about 10 per cent of all patients with PTC may have an affected relative; (2) when two or more patients in a family have PTC, all first- and second-degree relatives should be considered at risk; and (3) the disease appears to be frequently multifocal.

Thyroid gland volume in patients with breast cancer

S. G. Shering, A. P. Zbar, E. W. M. McDermott, P. P. A. Smyth and N. J. O'Higgins, *Departments of Surgery and of Medicine and Therapeutics, University College Dublin, St Vincent's Hospital, Dublin, Ireland*

The prevalence of non-toxic goitre and of asymptomatic thyroid gland enlargement (as determined by high-resolution ultrasonography) is significantly greater in patients with breast cancer than in age-matched controls. The significance of this observation is unknown. This study examined the relationship between thyroid volume and tumour characteristics in patients with breast cancer.

Thyroid volume was determined by high-resolution ultrasonography in 245 patients with a histological diagnosis of breast cancer over a 5-year period (1988–1993). All measurements were performed by one operator using a scanner fitted with a hand-held 7·5-mHz linear transducer. The volume of each thyroid lobe was calculated using the formula width × depth × length × 0·479.

Thyroid volumes were significantly greater in patients with axillary node-negative cancers ($P = 0{\cdot}04$, Mann–Whitney *U* test), larger breast tumours ($P = 0{\cdot}032$, Kruskal–Wallis test) and oestrogen receptor-positive tumours ($P = 0{\cdot}028$, Mann–Whitney *U* test). There was no clear association between thyroid volume and histological type or grade of the breast tumour. Patients with very large thyroid glands (greater than 30 ml) and very small thyroid glands (10 ml or less) had a significantly better outcome in terms of both disease-free ($P = 0{\cdot}005$, log rank test) and overall ($P = 0{\cdot}011$, log rank test) survival after a median follow-up of 4·6 years. Using the Cox proportional hazards model, thyroid volume was an independent prognostic factor when the effects of nodal status, tumour size and oestrogen receptor status were considered.

These findings have stimulated a search for factors that affect both thyroid volume and breast cancer progression.

Surgical goitres in adolescence and childhood: an update and audit

A. J. Webb, *Department of Surgery, The Royal Infirmary, Bristol, UK*

A series of young patients (up to and including 16 years of age) was presented to the Association in May 1990. It has been updated to cover the period 1967–1994 and now comprises 17 patients and 18 goitres. All have been studied in detail and the performance, at all stages, audited.

Some 20 surgical operations, including eight lobectomies and two near-total thyroidectomies, were carried out. The benign lesions included nodular goitre (four), non-toxic hyperplasia (three) and chronic lymphocytic thyroiditis (three). There were five neoplasms, namely follicular adenoma (three) and papillary carcinoma (two).

Significant problems in diagnosis, management or interpretation of histopathology arose in 12 of 17 patients.

Because of the rarity of goitres, and particularly neoplasms, in this age group and the reasonable assumption that no single centre in the UK will collect a sizeable series, some tentative conclusions from this audit are offered.

1. A standard and invariable investigation schedule should include ultrasonography and fine-needle cytology.
2. Clinical awareness of all goitres is necessary, but especially the possibility of non-toxic hyperplasia and chronic lymphocytic thyroiditis.
3. A surgical strategy for papillary carcinoma is required taking into account the variation in biological behaviour.
4. Joint management between paediatric oncologists and endocrine surgeons is necessary.

Thyrotoxicosis during pregnancy

A. Ghanaiem and P. Atkins, *Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

Twenty pregnant patients with thyrotoxicosis were managed by rendering them euthyroid with antithyroid drugs and performing bilateral subtotal thyroidectomy during the middle trimester.

All patients delivered normal babies. There has been no recurrence of thyrotoxicosis over a mean follow-up of 7 years. After surgery, all patients were treated with thyroxine until after delivery, when it was withdrawn. Four patients have subsequently needed long-term thyroxine. No patient had recurrent laryngeal nerve injury. Two patients were hypocalcaemic after surgery and one remains on calcium supplements 8 months after surgery.

Subtotal thyroidectomy remains an attractive form of treatment for thyrotoxicosis in pregnancy; the thyrotoxicosis is rapidly cured and normal pregnancy and delivery ensue.

Initial experience of the NIM 2 nerve integrity monitor in thyroid and parathyroid surgery

J. Barwell, D. Wilkins, J. Little and R. Page, *Department of Surgery, Derriford Hospital, Plymouth, UK*

The efficacy of the nerve integrity monitor (NIM 2), as perceived by the operating surgeons, in protecting the recurrent laryngeal nerve during thyroid and parathyroid surgery was assessed. Changes in surgical, anaesthetic and theatre staff practices that are necessary in implementing its use were evaluated.

Fifteen recurrent laryngeal nerves in 11 patients were dissected by three surgeons during operations in a general surgical service setting. Using a pro forma, surgeons were asked to score (on a scale of 1 to 10) their assessment of the help provided by the nerve integrity monitor during various parts of the operation. Anaesthetic staff were asked to comment on any variations imposed on their first choice of anaesthetic and delays that resulted Increases in theatre staff workload were also recorded for each patient. A clinical assessment of preoperative and postoperative (immediate and 6-week) vocal cord function was made.

Thirteen of the 15 nerves were successfully identified by the integrity monitor. Faulty endotracheal tube electrodes were the cause of failure in one patient. In the other, a parathyroid adenoma was found lying in a superficial position and dissection of the nerve, therefore, did not proceed. In the 13 completed patients, surgeons scored a mean of 8·6 for help in confirming visualization of the nerve and 9·1 for help in demonstrating an intact nerve at the end of the procedure. However, a mean score of only 2·9 was given for help in identifying the nerve before visualization.

Induction of anaesthesia was increased by an average of 10 min and a mean of 38 min of extra theatre staff time was associated with each patient on whom the monitor was used. The main anaesthetic problems reported were that the purpose-built endotracheal tube was too soft, permitting kinking and obstruction. The positioning marks on the tube were not clearly visible. Some anaesthetists considered it a disadvantage that paralysing agents could not be used during the procedure. Not surprisingly in this small study, no recurrent laryngeal nerve damage was suspected on clinical findings after operation

The integrity monitor effectively demonstrates an intact recurrent laryngeal nerve at the end of surgery (possibly of medicolegal significance). It does not help the surgeon in actually finding the nerve. Confirmation of the visualized nerve by the integrity monitor, while reassuring, cannot remove the risk to its branches (which occur in 58 per cent of specimens) during further dissection. For routine thyroid and parathyroid surgery, the NIM 2 nerve integrity monitor should be regarded as a medicolegal aid rather than a surgical tool.

Examination of vocal cords by videolaryngostroboscopy before and after thyroid operations

S. Kocak, I. Kocak, S. Ozbas, S. Aydintug and S. Baskan, *Departments of Surgery and Ear, Nose and Throat, Ankara University Medical School, Ankara, Turkey*

Vocal cord paralysis is one of the most serious complications of thyroid surgery. Routine dissection and demonstration of the recurrent nerve is controversial. The superior laryngeal nerve should be preserved by careful dissection and ligation of the branches of the superior thyroid vessels. The reported rate of primary recurrent nerve paralysis with the visualization method is about 3 per cent. The palsy is permanent in one-third. Indirect laryngoscopy is not sufficient to differentiate temporary from permanent paralysis. Injuries to the external branch of the superior laryngeal nerve are not easily diagnosed when examination of the vocal cords is performed by indirect laryngoscopy.

Indirect laryngoscopy and videolaryngostroboscopy (VLS) were performed in 108 patients before and after thyroidectomy as a prospective study. Nine patients developed voice disturbance after operation, which was permanent in one. VLS was carried out in another 18 patients with hoarseness after thyroidectomy, who were not evaluated before operation.

Superior and inferior laryngeal nerve injuries, laryngeal injuries due to endotracheal intubation and other laryngeal disturbances were differentiated by VLS but rarely by indirect laryngoscopy. VLS was also successful in diagnosing temporary and permanent vocal cord paralysis.

VLS should be performed in patients with voice disturbance after thyroidectomy.

Management of thyroglossal cyst

A. Ghanaiem and P. Atkins, *Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

Diagnosis of thyroglossal cyst was made in 30 patients. Ultrasonography was undertaken in 21 and technetium scan in 12.

The findings at operation and subsequent histological analysis confirmed the diagnosis of thyroglossal cyst in 28 patients. Two patients had thyroid adenoma; both lesions had been shown on ultrasonography to be partly cystic.

One patient with a thyroglossal cyst was shown to have a papillary carcinoma in the wall of the cyst. Sistrunk's procedure was undertaken in all but two patients. The patient with a papillary carcinoma subsequently underwent total thyroidectomy and foci of carcinoma were found in both lobes.

Surgery was complicated by postoperative haemorrhage in one patient and a thyroglossal fistula recurred in one patient with a thyroglossal cyst in whom Sistrunk's procedure was not undertaken.

Surgery for thyroglossal cyst should always include removal of the middle of the hyoid bone but Sistrunk's procedure may not be adequate treatment if the cyst wall contains a papillary carcinoma.

Randomized comparison of agents for caudal anaesthesia in anal surgery

Sir

In their Short Note (*Br J Surg* 1996; 83: 364–5), Dr Adebamowo and his colleagues suggested that caudal epidural anaesthesia using 2 per cent lignocaine with 1 : 100 000 adrenaline produced adequate sensory block of faster onset and longer duration than that with 2 per cent lignocaine plain or 1 per cent lignocaine with 1 : 100 000 adrenaline These observations are not new While the present findings are accepted tenets in regional anaesthesia[1–3], we believe their data do not support this conclusion

The primary mechanism of caudal epidural anaesthesia is spinal root block Local anaesthetic injected into the caudal space must diffuse across the meningeal barrier (dura) before conduction block is possible. Clearly, the more concentrated the local anaesthetic solution, the steeper the diffusion gradient and the faster the onset time. Similarly, concentrated local anaesthetic solution delays the reversal of the gradient and the longer the block lasts. However, dural transfer of anaesthetic molecules is also a function of the caudal epidural anaesthetic mass (i.e. total dosage)[4]. Hence, it is not surprising, for example, that prilocaine given epidurally either as 30 ml 2 per cent solution or as 20 ml 3 per cent solution failed to demonstrate any significant difference in onset time or duration of anaesthesia[5]. Therefore, while the volume of caudal injection is not known in this study, we believe it is impossible to interpret the present data. A proper experiment comparing local anaesthetic solutions of different concentrations should keep the total dosage constant.

With regard to the role of caudal adrenaline, it is now well established that the minimal effective concentration for its use in epidural anaesthesia is about 2·5 μg/ml (1 : 400 000). It appears that increasing the dose beyond 5 μg/ml (1 : 200 000) provides no additional benefit[6]. While most adult caudal injection for anal surgery requires a volume of 20–30 ml, we are concerned that local anaesthetic solution with adrenaline 10 μg/ml (1 : 100 000) is potentially dangerous and increases the likelihood of side-effects.

Despite the reported complications, we are most impressed with the authors' results. We are also encouraged by the fact that non-anaesthetists have taken interest in regional anaesthesia. However, we wish to stress that major regional anaesthesia could produce important physiological changes and local anaesthetic toxicity, thereby contributing to patient morbidity and mortality. It is our policy to prevent any person from assuming dual responsibility as both the surgeon and the proceduralist[7]. It is important that during any form of major regional anaesthesia, a qualified person dedicated to patient monitoring and resuscitation must be present throughout the procedure and until the potential for local anaesthetic toxicity has passed.

Author's reply

Sir

We thank Drs Chan and Lam for their interest in our paper. The dose of local anaesthetic solution was indeed constant at 2 mg/kg – this fact was inadvertently omitted during the editorial process.

The choice of agents used was based on readily available preparations to avoid non-availability being used as a reason for non-use of this technique. Dilution of the 2 per cent lignocaine with 1 : 100 000 adrenaline to give 1 per cent with 1 : 200 000 is what we now use for our study, which is still continuing; results so far are satisfactory.

Our aim is to popularize a simple and economical technique associated with low morbidity and mortality rates in answer to a call for the same[1]. It is our belief that the technique will also be useful in those parts of the world where anaesthetists are still a luxury[2]. We certainly agree with Drs Chan and Lam that the results are impressive and this should encourage wide adoption of the technique.

Laparotomy for abdominal sepsis in the critically ill

Sir

We read with interest the article written by Mr Anderson and his colleagues (*Br J Surg* 1996; **83**: 535–9). The authors have presented a large number of severely ill patients: the APACHE (Acute Physiology and Chronic Health Evaluation) II scores averaged 24, which is considerably higher than those mentioned in comparable studies documenting the severity of disease. Although Anderson *et al.* promised alternative approaches, they categorically abandoned the concept of relaparotomy on demand, although this retains its original advantages.

Our own studies and those of others[1–3] have shown that the mortality rate following relaparotomy on demand is higher than that associated with planned relaparotomy because of the delay. The only clear-cut indication for relaparotomy is multiple organ system failure (MOSF), but the decision to perform a relaparotomy must be made as soon as possible and certainly before MOSF becomes evident[1].

Recently Hau *et al.*[4] achieved significantly better results in patients treated by relaparotomy on demand *versus* planned relaparotomy regarding postoperative MOSF and infectious complications. Surgical treatment of abdominal sepsis is like finding the passage between Scylla and Charybdis. On the one hand it is important to do as little as possible, on the other hand it is essential to find out whether the patients are prone to persisting abdominal infection in spite of surgical cleansing at the initial operation. These patients are immunologically impaired because of initially high APACHE II scores, delay in diagnosing peritonitis or advanced age (more than 70 years). The relatively small proportion of patients in whom the source of infection was eradicated (62 per cent) can be explained by the fact that 66 per cent of patients in the study of Anderson *et al.* fulfilled the above mentioned criteria. This connection underlines the importance of defining patients who will not profit from initial surgical sanitation because of immunological impairment. That would help to reduce the interval before further operation.

The therapeutic use of planned laparotomies was selected in our department for patients with a source of infection that cannot be eradicated at initial operation. However, because we were not able to define immunologically impaired patients early in the course of disease, we used relaparotomies on demand in patients in whom initial operation had successfully eradicated the source of infection. The decision to perform a relaparotomy was made if there was no clinical improvement within the first 48 h, or if there was clinical deterioration.

In summary, we think that a prospective trial among patients with severe abdominal sepsis as requested by Anderson *et al.* is neither justified nor feasible.

Author's reply

Sir

We thank Drs Koperna and Schulz for their comments Interpreting the available literature is difficult because of lack of comparative studies, and international differences in both practice and disease severity among patients admitted to intensive care units. We would agree that the patients studied in our series were at least as old and as sick as any reported elsewhere, and this fact undoubtedly contributed to the high mortality rate. We cannot agree, however, that we advocated the wholesale abandonment of the laparotomy-on-demand approach. We simply pointed out that within our practice this approach is inevitably associated with some delay in the diagnosis of further or continuing abdominal sepsis, and that inadequate treatment of this is almost always fatal.

The question we seek to address is whether more aggressive surgical intervention can improve outcome. As we indicated in the paper, several subgroups of patients emerge in whom overwhelming clinical factors will be the principal determinant of outcome, almost irrespective of the treatment course followed. Thus, there exists a group of some 18 per cent who are too elderly and frail to survive the disease process even in the face of 'successful' surgical and intensive care treatment. There is a group of predominantly elderly and acutely unwell patients (mean APACHE II score of more than 29), the majority of whom pursue a remorseless, downward path and who are also unlikely to respond to any currently available therapy. These patient groups will overlap those with organ failure, some of whom have continuing abdominal sepsis, and among these will be patients with severe immunological impairment as alluded to, but not defined by, Drs Koperna and Schulz. The literature does not indicate the optimal means of surgical treatment for those with continuing abdominal sepsis, although some form of improved abdominal cleansing is necessary. The study reported by Hau *et al.*[1] showed a higher mortality rate in patients undergoing planned relaparotomy when compared with those being treated by laparotomy on demand, but it is relevant that the mean age and mean APACHE score were significantly lower than those of our own patients. Furthermore, given that Hau *et al.* achieved clearance of sepsis in more than 90 per cent of their patients subsequently treated by relaparotomy on demand, one has to wonder what they hoped a further operation would achieve. The same message expounding the risks of surgical over-treatment among critically ill patients by an alternative technique, namely laparostomy, was highlighted by our department some 10 years ago[2].

Given that our surgical treatment of these patients is not perfect and that inadequate treatment is fatal, it seems sensible to mount a comparative investigation to try to identify a path forward. We are under no illusions as to the difficulty of this task, the large number of confounding factors, the explicit need for targeting any further operation on the appropriate patient group, and the relatively modest impact on overall survival that one could hope to achieve.

Possible entry criteria could include incomplete abdominal cleansing at first operation, APACHE score more than 20, delayed diagnosis (over 48 h) of generalized peritonitis and presence of multiple organ failure. One, or at most two, further lavages could be supported.

A better bridge for loop stomas

Sir

We were interested to read the Surgical Workshop by Mr Cochrane and colleagues (*Br J Surg* 1996; 83: 365). We favour the use of a Convatec (Convatec, Ickenham, UK) rod which does not require skin fixation. This rod is introduced under the loop of bowel using a Jaques' catheter with minimal trauma to the bowel[1]. The advantage of this technique is that it not only holds the bowel onto the surface of the skin satisfactorily, but also allows easy placement of the stoma bag adjacent to the bowel without the interference of a skin suture. In addition it is cheap, costing UK £1.70 per rod.

Infiltration of the gallbladder bed during laparoscopic cholecystectomy

Sir

A recognized method of facilitating bloodless dissection of the gallbladder from its liver bed during open cholecystectomy is to inject a solution of adrenaline between the gallbladder and its covering layer of peritoneum. We employ a similar technique during laparoscopic cholecystectomy

Once the cystic duct and artery have been safely divided, the gallbladder is placed on tension in preparation for dissection from the liver bed. A fine spinal needle is introduced through a puncture wound in the anterior abdominal wall under direct vision, and the tip is carefully inserted into the space between the gallbladder and its peritoneal covering. A 20-ml mixture of 0·5 per cent bupivacaine and 1 : 200 000 adrenaline is diluted with an equal volume of saline and injected, opening the space between the two structures. After a moment's pause, the gallbladder can then be dissected from the liver with scissors using minimal diathermy.

We find that this simple technique, by opening up the plane of dissection, allows quick and easy removal of the gallbladder from the liver bed. The amount of bleeding from the liver bed is reduced, and the infiltration may also contribute to the control of postoperative pain. The needle can also be used to aspirate bile from a distended gallbladder. We have experienced no complications from the technique, which we have used as part of our routine procedure in over 300 operations.

Number of lymph node metastases is significantly associated with survival in patients with radically resected carcinoma of the ampulla of Vater

Sir

We read with interest the article by Dr Roder and colleagues (*Br J Surg* 1995; 82: 1693–6), who found that the number of involved lymph nodes affects survival after radical resection for ampullary cancer: patients with zero to two positive nodes had an actuarial 5-year survival rate of 41 per cent, while no patients with three or more positive nodes survived beyond 30 months. We recently reported that both no positive nodes and one to three positive nodes are favourable prognostic factors after such radical resection, with 5-year survival rates of 81 and 71 per cent respectively[1]. Both studies independently showed the effectiveness of radical surgery for patients with up to two or three positive nodes. Thus, we agree with the conclusion of Dr Roder and colleagues that 'radical resection and lymphadenectomy should be the treatment of choice for patients with tumours of the ampulla of Vater'. Unlike patients with breast cancer, those with ampullary cancer may benefit substantially from radical surgery However, it remains unclear whether more radical lymphadenectomy is effective for those with four or more positive nodes.

Dr Roder and colleagues did not discuss the impact of the location of positive nodes on survival. We have previously reported that patients with metastases confined to the pancreatoduodenal nodes have a significantly improved survival (5-year survival rate of 67 per cent) compared with those with metastases to the superior mesenteric nodes (5-year survival rate of 27 per cent)[1]. During the past decade, we have performed dissection of the superior mesenteric nodes to the right of the superior mesenteric artery for this disease, with the exception of 'early cancer', defined as cancer not penetrating the sphincter of Oddi[2]. In addition, we have dissected para-aortic nodes in patients with advanced disease clinically suspected of having positive regional nodes. As a result of this aggressive stance, three patients with positive superior mesenteric nodes have survived for 5 years[1]. Although the follow-up period in our series remains short, the value of radical lymphadenectomy should be clarified with the increase in long-term survivors with positive nodes.

Authors' reply

Sir

We appreciate the comments of Drs Shirai, Ohtani and Hatakeyama confirming our observations on the effect of the number of involved lymph nodes on survival in patients after radical resection for ampullary carcinoma. We do not, however, agree with their comments regarding location of positive lymph nodes and survival. In our experience, now over 70 patients who have had a radical resection for carcinoma of the ampulla of Vater, we rarely observed positive lymph nodes at or along the superior mesenteric artery In contrast, more than 85 per cent of the positive nodes were located in the para-aortal region, i.e. lymph node station 13 of the Japanese Society for Biliary Surgery. On multivariate analysis only the number of positive lymph nodes, not the location of nodes, emerged as an independent prognostic factor. Further studies are, therefore, necessary before extensive lymphadenectomy along the superior mesenteric artery can be recommended as standard for patients with ampullary cancer and extensive lymph node metastases.

Single-stage treatment for malignant left-sided colonic obstruction: a prospective randomized clinical trial comparing subtotal colectomy with segmental resection following intraoperative irrigation

Sir
I enjoyed the paper by the SCOTIA Study Group (*Br J Surg* 1995; 82: 1622–7). Since intraoperative colonic cleansing was introduced, left segmental colonic resection and primary colocolic anastomosis has become much less of a technical problem, but pathological conditions of the colonic wall, such as ischaemia, oedema, inflammation and ulceration, can still limit the performance of single-stage operations. Local mucosal changes may be accompanied by impaired healing of the primary anastomosis and the local mucosal condition of the colon should be evaluated at operation. The commonest finding is non-occlusive ischaemia[1] caused by raised intraluminal pressure in the obstructed colon or by circulatory shock. The first layer affected by hypoxia is the metabolically active mucosa. The initial histopathological change is subepithelial gaps. Next, the epithelium is sloughed and shed down to the base of the crypts[2]. Third, oedema develops and a membrane of necrotic epithelium covered by fibrin and infiltrated by inflammatory cells and bacteria appears. At this point the changes become macroscopically visible. Disintegration of the lamina propria is accompanied by severe oedema, ulceration and bleeding. If the muscularis and serosa are involved, gangrene and perforation may result.

Retrospective evaluation of 22 consecutive patients with left-sided colonic obstruction (personal data) has indicated that the primary anastomosis healed without problems in the absence of any macroscopic mucosal changes. However, in five patients anastomotic failure was associated with changes resembling those of radiation colitis, mucosal ulcers, inflammation involving the serosa and colonic perforation with severe peritonitis. The presence of macroscopically visible changes correlated well with the patient's circulatory condition (American Society of Anesthesiologists grade III and IV), the inflammatory parameters detected before operation, and with weight of colonic content over 3 kg (evacuated before the peroperative irrigation was started). Based on these retrospective findings, a single-stage procedure was performed in six subsequent patients in whom no macroscopic mucosal changes could be detected; all healed without leakage. As an alternative, a Hartmann's procedure was undertaken because of mucosal ulcers in one patient and tumour infiltration of the urinary bladder in another. Subtotal colectomy was performed due to mesocolic panniculitis in a third patient[3].

Macroscopic mucosal changes might, therefore, be the limiting factor for primary left-sided colonic anastomosis in patients with acute obstruction but this conclusion remains to be tested in a randomized study.

Aortic prosthetic infection: 50 patients treated by radical or local surgery

Sir
The article by Mr Hannon and colleagues (*Br J Surg* 1996; 83: 654), gave us important guidelines in the management of this difficult problem. During the past 5 years there has been considerable enthusiasm to try to prevent prosthetic graft infection by soaking the graft in rifampicin. Unfortunately, I have found that even this practice does not prevent graft infection. I recently had a patient who developed graft sepsis shortly after having a rifampicin-soaked graft inserted. The infecting organism was enterococcus, which was resistant to rifampicin.

Role of cytokines and growth factors in promoting the local recurrence of breast cancer

Sir
We read with interest the Review by Mr Reid and colleagues (*Br J Surg* 1996; 83: 313–20). The authors suggested that local recurrence in breast cancer could be attributed to growth factors and cytokines, derived from the surgical field environment, acting on free cancer cells (shed locally or systemically) and dormant residual cancer cells in the vicinity, thus causing local recurrence. They did not specify which factors and cytokines could mediate the process, but considered the local recurrence phenomenon in breast cancer to be different from that of other cancers bearing in mind that breast cancer is oestrogen-dependent

We would like to suggest that the higher aromatase activity and oestrogen concentration in the tumour-bearing quadrant of the breast (*versus* other breast quadrants) creates a pro-cancer environment favouring local recurrence near the surgical field. Growth factors and cytokines, particularly interleukin (IL) 6, play an important role in the regulation of oestrogen-synthesizing enzymes.

In addition, the macrophages and lymphocytes infiltrating the surgical field as part of the response to wound healing may secrete cytokines such as IL-6, which stimulate oestrogen synthesis in the area of the surgical field, thus raising local oestrogen concentration.

During the past few years, evidence has accumulated demonstrating that breast cancers produce growth factors and cytokines, which stimulate the enzymes involved in oestrogen synthesis (aromatase, oestradiol, dehydrogenase and oestrone sulphatase) to promote an oestrogenic environment favouring tumour growth[1]. Insulin-like growth factor (IGF) type I, IGF-II, IL-1β, IL-6 and tumour necrosis factor (TNF)[1] and TNF-α have been shown to stimulate the enzymes involved in oestrogen synthesis[2,3].

There is now a convincing body of evidence indicating that breast tumour location has an effect on aromatase activity in adjacent tissues[4,5]. The aromatase activity, and hence oestrogen synthesis, was found to be significantly higher in breast tumour-bearing quadrants than in other quadrants[4,5]. This finding was further supported by evidence of increased aromatase gene expression in breast tumour-bearing quadrants[6].

Miller and Mullen[7] have reported that IL-6 has an important stimulatory effect on aromatase activity in cultured tumour-derived fibroblasts Purohit *et al.*[5] showed that aromatase activity was increased in tumour-bearing quadrants, and this activity correlated with increased production of IL-6 by the tumour tissue. IL-6 may be produced by the cancer cells, the tumour fibroblasts and/or the macrophages and lymphocytes infiltrating around and within the tumour.

As it is known that macrophages and T lymphocytes (TH2) secrete IL-6, and that up to 50 per cent of the breast tumour volume may be composed of macrophages and lymphocytes, it is logical to assume that these cells secrete IL-6 (and other factors or cytokines) which stimulates oestrogen synthesis in the tumour-bearing quadrant. This hypothesis is supported by recent findings that the incidence of breast cancer was significantly reduced (by 25 per cent) among patients who had undergone transplantation receiving therapeutic immunosuppression[8], and that tamoxifen decreased the CD4 . CD8 ratio[9].

The lower local recurrence rate associated with quadrantectomy as compared with more conservative wide local excision[10] is consistent with our hypothesis. The macrophages and lymphocytes also infiltrate the surgical field as part of the healing response These cells may secrete cytokines, such as IL-6, which stimulate oestrogen synthesizing enzymes in the area, thus contributing to the creation of a pro-cancer environment encouraging local recurrence. However further research is required to confirm our suggestion and to provide a better understanding of the complex molecular events involving growth factors and cytokines in the local recurrence phenomenon of breast cancer

Future modulation of these factors and cytokines may provide a new means of improving local control

Ileocaecostomy: an alternative surgical procedure for antegrade colonic enema

Sir

The article by Messrs March and Kiff (*Br J Surg* 1996; 83: 507–8) describes the novel approach of using the terminal ileum as a catheterizable conduit to allow antegrade colonic irrigation, with the ileocaecal valve as the mechanism preventing reflux of bowel contents and irrigant fluid.

While this is an interesting concept, we have some reservations. The ileocaecal 'valve' mechanism is incompletely understood, but available physiological evidence in man suggests that it does not act as a sphincter with persistent tonic contraction. Rather it exerts its sphincteric effect via variation in the rate of phasic contractions that occur over a considerable length of the terminal ileum, and are modulated by reflexes dependent on caecal and ileal integrity[1]. Caecal distension increases and ileal distension decreases the rate of these 'sphincteric' contractions. There are considerable periods of time when the ileocaecal 'valve' is relaxed, and reflux freely occurs from the caecum into the terminal ileum. The authors use only 5–7 cm of the distal ileum for their conduit This short segment combined with the separation from the remainder of the terminal ileum and its neurological influences is likely to disrupt the sphincteric mechanism of the ileocaecal junction and compromise its ability to act effectively as a continence mechanism

We were also surprised that the authors make no mention of an alternative operation, the continent colonic conduit, which we have previously described as another way of effecting antegrade colonic irrigation[2,3]. The colonic conduit has the theoretical advantage over the appendicostomy and the ileocaecostomy in that it can be constructed in the colon in a position most suited to deal with the underlying physiological abnormality. In cases of chronic constipation due to outlet obstruction, it can be formed in the descending or sigmoid colon. In cases of slow transit, it can be made in the ascending or transverse colon This manoeuvre obviates the need to irrigate the whole of the colon, which we believe to be unnecessary.

Some patients with appendicostomies have suffered abdominal pain and cramps that are thought to be due to the retrograde passage of irrigant fluid into the terminal ileum[4]. In addition, many find it necessary to administer phosphate enemas per conduit to achieve evacuation. There are reports of acute hyperphosphataemia and hypocalcaemia occurring with such enema usage[5–8]. Complications of this kind may be more likely in patients with an ileocaecostomy where there is no resistance to the passage of irrigant fluid through the ileocaecal anastomosis. We believe our conduit (which leaves the ileocaecal region intact) reduces the likelihood of caeco–ileal reflux.

The article does not give any detail of the size or appearance of the ileocaecostomy. The accompanying unscaled photograph suggests that the ileal mucosa is proud to the abdominal skin, which may reduce the cosmetic acceptability of the operation. The length of follow-up without stomal stenosis is not stated, but it is probable that a group of only seven patients does not represent a large enough sample to have the power to exclude such complications.

To prevent stenosis, we create a catheterizable conduit with a recessed orifice which is invariably less than 10 mm in diameter. This technique uses a V–Y flap of skin similar to that previously described[7]. All our patients have found the conduit cosmetically acceptable yet easy to intubate, and we have had only one episode of stomal stenosis in 20 patients at a median follow-up of 20 (range 7–37) months. Others have also found that some form of plastic skin flap construction reduces the incidence of stomal stenosis[5–8].

Although the authors only describe the use of their procedure in chronic idiopathic constipation, antegrade colonic irrigation has been successfully used for the treatment of faecal incontinence[2,4–7] Surgeons tempted to use the ileocaecostomy in the management of incontinence should be cautioned. If the procedure fails and surgical revision is required, the absence of the ileocaecal valve mechanism may exacerbate incontinence, resulting in a situation worse than before operation.

Comparison of venous reflux in the affected and non-affected leg in patients with unilateral venous ulceration

Sir

Mr Bradbury and his colleagues have highlighted the importance of the popliteal vein segment in chronic venous ulceration (*Br J Surg* 1996; 83· 513–15) Using similar patient inclusion criteria (unilateral ulceration only, no previous ulceration in the contralateral leg, no evidence of arterial insufficiency, rheumatoid arthritis or diabetes mellitus), we have studied the colour flow duplex ultrasound results of 49 patients presenting to the community-based leg ulcer clinics in East Gloucestershire. The results are given in *Table 1*.

Table 1 Patterns of venous reflux in the ulcerated and non-ulcerated limbs of patients with unilateral ulceration.

	Ulcerated legs reflux	Non-ulcerated legs reflux	P*
CFV/SFV	9	2	—
Popliteal vein	18	9	0·07
LSV			—
Origin	35	29	—
Lower thigh	34	26	—
Below knee	27	11	0·02
SSV	10	8	—

CFV, common femoral vein; SFV, superficial femoral vein; LSV, long saphenous vein, SSV, short saphenous vein. *Corrected χ^2 test

It is confirmed from these early results of our ongoing prospective study that reflux in the superficial venous system below the knee, including the calf perforators, is also significantly greater in ulcerated than non-ulcerated limbs. The role of operation in chronic venous ulceration, including subfascial endoscopic perforator ligation, remains unclear, and further investigation is indicated.

Authors' reply

Sir

We thank Messrs Ghauri, Grabs, Nyamekye and Poskitt for their interest in our recent article, and are interested to note that they too found an increased prevalence of popliteal vein incompetence in the affected legs of patients with unilateral leg ulceration of apparently 'pure' venous aetiology However, in addition to excluding patients in whom non-venous aetiological factors had been identified, we also excluded patients who had undergone previous venous surgery. We felt that this was extremely important if we were to achieve a true comparison of reflux between ulcerated and non-ulcerated legs that had not been previously 'tampered' with surgically. The surgical history of the patients in Mr Poskitt's series was not stated in his letter, but previous varicose vein surgery in some of his patients might possibly account for differences between his series and ours, with respect to the prevalence of superficial venous incompetence. Thus, Mr Poskitt and his colleagues may have found a lower incidence of superficial venous incompetence in the non-ulcerated legs because their patients had previously undergone saphenous and/or perforator ligation on that side. With respect to perforators and their ligation, we agree that this is an area that is in urgent need of further scientific investigation, particularly with the increasing popularity of subfascial endoscopic perforator surgery.

Correlation between Acute Physiology and Chronic Health Evaluation (APACHE) III score and immunological parameters in critically ill patients with sepsis

Sir

We read with interest the paper by Dr Rogy and colleagues (*Br J Surg* 1996; 83: 396–400) describing physiological and immunological parameters in ten critically ill patients. We performed daily Acute Physiology and Chronic Health Evaluation (APACHE) III scoring and C-reactive protein (CRP) measurement on five consecutive patients with severe acute pancreatitis admitted to intensive care in the second half of 1995. APACHE III scores and CRP measurements at admission and 72 h are shown in *Fig 1* together with patient demographics and outcome.

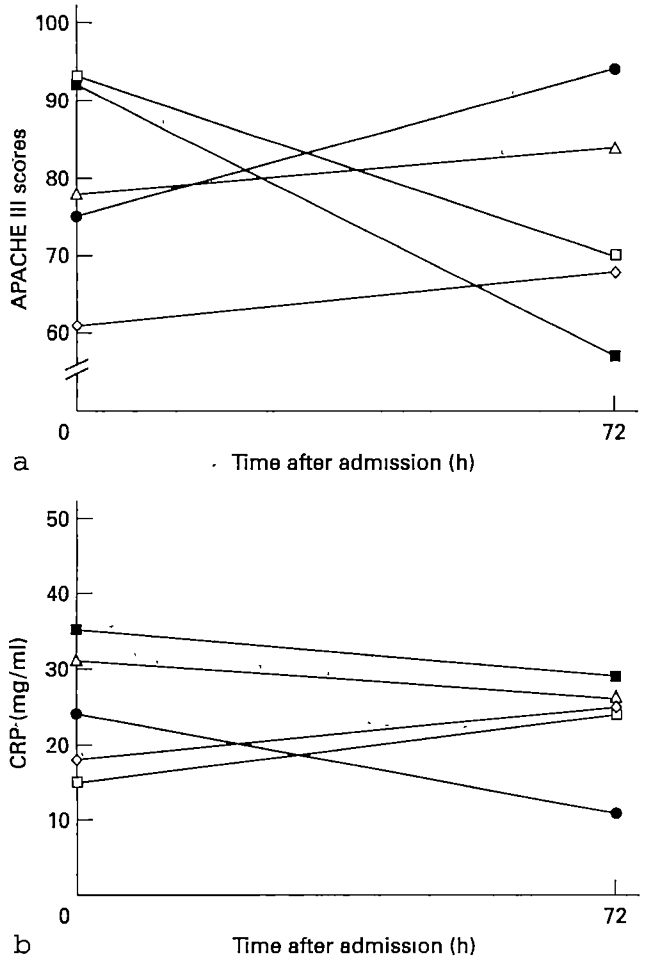

Fig. 1 Changes in APACHE III score and CRP in five patients with severe acute pancreatitis between intensive care admission and 72 h. ◇, 65-year-old man who left intensive treatment unit (ITU) on day 90; □, 39-year-old woman who left ITU on day 57 but later died; ■, 65-year-old man who died on day 14; ●, 65-year-old man who died on day 23; △, 80-year-old woman who left ITU on day 25

We found no correlation related to outcome in this small group with pancreatitis. Any correlation in a larger sample would be unhelpful for prediction of outcome because of individual variation.

We cannot support the findings of Rogy *et al.* that APACHE III scoring at 72 h predicts the outcome of critically ill patients when applied to severe acute pancreatitis.

Author's reply

Sir

We find no reason to quibble with the observations of Messrs Barber and Armstrong. Indeed, there is currently no statistical basis on which to assume that any physiological scoring system will track the course of patients with evolving inflammatory disease. However, our observations were derived from patients with infection. It is neither intuitively nor statistically unlikely that such patients might exhibit an acute reduction in physiological scoring in response to specific antimicrobial and resuscitative efforts[1]. Rather, we were impressed to find that immunocyte function was acutely responsive in this setting.

Book reviews

Electrosurgery in Operative Endoscopy

A. Wattiez, S. Khandwala and M.-A. Bruhat. 250 × 175 mm. Pp. 274. Illustrated. 1995. Oxford: Blackwell Science. £49.50.

The authors rightly state that knowledge of electrical principles among most surgeons is very limited; the aim of this book is to correct this deficit. Written in a not overly-technical style, the authors have tried to keep the theoretical aspects to a minimum while concentrating on practical aspects of electrosurgery. By and large they have succeeded. The first half deals with the fundamentals of electrical energy, electrosurgical waveforms and the creation of different tissue effects, and monopolar and bipolar electrosurgery. While amply illustrated with line drawing and diagrams, the circuit diagrams at the beginning of the book may be off-putting to those without a background in physics. There are individual chapters on electrosurgery in laparoscopy, laparoscopic sterilization, endoscopic excisional surgery and underwater surgery (i.e. urological and gynaecological surgery). The slight bias towards gynaecological surgery probably reflects the background of the authors. Contributions from other endoscopic surgeons might have given a broader overview. The aetiology and prevention of accidental electrosurgical burns is the most important topic in this book and is well covered. There are also chapters on the effects of electrosurgery-induced electromagnetic interference on electrocardiograms, pacemakers and videoimaging equipment. Comprehensive references are given as well as a list of recommended practices. A chapter defining the role of theatre nurses in electrosurgical safety is also included. Although aimed specifically at the endoscopic surgeon, much of the contents is of relevance to other surgical specialties. The best way to prevent injuries is to understand them, and in this respect, the authors have succeeded in their aim.

Laparoscopic Colorectal Surgery

J. W. Milsom and B. Böhm. 260 × 180 mm. Pp. 256. Illustrated. 1996. New York: Springer. DM168.

This book is well written, very readable and extremely topical. The subject is introduced with a comprehensive history of laparoscopic surgery and then follow seven chapters concerning equipment, instruments, tissue dissection and techniques both for basic laparoscopic surgery and for the advanced and specialized field of coloproctology. Precise details are given of intra-abdominal suturing techniques, port insertion, cannula site closure, indications and postoperative management Curiously, the chapter on major operative procedures in laparoscopic colorectal surgery begins with ileal resection. The rest of this chapter describes the laparoscopic techniques of ileocolectomy, right hemicolectomy, proctosigmoidectomy, abdominoperineal resection and total abdominal colectomy. The last procedure is concluded by a double-stapled ileorectal anastomosis with no reference to, or description of, an ileal pouch. The subsequent two chapters are concerned with the fashioning and closure of stomas, suture rectopexy for prolapse and adhesiolysis. The final chapters concern advantages and disadvantages of laparoscopic colorectal surgery, and the education of the surgical team in the technique and practice of the new operations.

For the surgeon embarking upon laparoscopic colorectal surgery this book is essential reading; particularly pertinent are the excellent sections on the training and skills necessary. Unfortunately, the actual operative descriptions are not as comprehensive as might be expected. Of the operative diagrams of the positioning of the theatre team and the port sites, too much space has been incorporated and most are full-page and repetitious. There are only line diagrams of the techniques, which are technically clear and good, but could be improved on if associated with colour photographs which are strikingly absent. Some techniques are missing, notably the mesh rectopexy, retroperitoneoscopy and colectomy without pneumoperitoneum. Stoma construction is well described and the diagrams throughout are clear and of the highest standard.

Although claimed to be the first surgical text on the subject, it compares unfavourably with the book, published a year ago and with the same title, edited by Monson and Darzi, which is superbly illustrated with colour photographs of operative techniques.

Shackelford's Surgery of the Alimentary Tract. 4th ed. (5 volumes)

G. D. Zuidema, M. B. Orringer, W. P. Ritchie Jr, J. G. Turcotte, R. E. Condon and L. M. Nyhus (eds). 285 × 220 mm. Pp. 556 (Vol. 1), 423 (Vol. 2), 670 (Vol. 3), 474 (Vol. 4), 652 (Vol. 5). Illustrated. 1996. Philadelphia, Pennsylvania: W. B. Saunders. £330.

This five-volume set presents a fairly detailed and up-to-date treatise on gastrointestinal surgery. Although it is the fourth edition, surprisingly it is relatively unknown on the European side of the Atlantic. It has grown from a single-editor edition in 1955 through a multieditor to a multiauthor fourth edition now.

It is, on the whole, well written and the depth of coverage in general includes considerable operative detail. Despite a largely American authorship, references and text have an international flavour and the British reader will find much that is familiar and little to quarrel with. It claims to provide an authoritative and up-to-date text which is valuable because of 'dramatic changes in surgical practice during the past few years'. It achieves this objective in part but it is disappointing to find some chapters rather superficial. The one on intestinal intubation is somewhat dated and others, such as those on basic sciences and operative surgery in volume 4, 'Colon and Rectum', somewhat limited in scope. On the other hand, several chapters are outstanding. They include those on anatomy and physiological diagnostic studies and the complications of oesophageal surgery in volume 1. The chapter on anatomy in volume 2 is excessively detailed in comparison with that in volume 4 where the text is somewhat limited by the space available. The general appearance of the book would have benefited from some colour illustrations, especially for anatomical specimens and histology.

The set suffers from the common problem of variability of quality, which is seen in all multiauthor books. There are 50 or more authors writing in each volume and their variability of style is reflected by the chapter reference lists which vary from a limited and rather dated six to in excess of 350. Unfortunately the long lists of references provide a comprehensive rather than a critical review of the literature and indicate only the accessibility of the author to computerized Medline.

This work is in competition with several other excellent state-of-the-art surgical texts and so will probably remain popular only in the USA. At UK £330 for the five-volume set, it will grace the shelves of only the most affluent surgical libraries in the UK; there the surgical trainee may find much of interest while the specialist may find it reassuring rather than informative.

Textbook of Surgery

Roshan Lall Gupta. 273 × 215 mm. Pp. 677. Illustrated. 1996. New Delhi: Jaypee Brothers Medical Publishers. Price not provided.

This is an all encompassing textbook of surgery from the Indian subcontinent The self description says that it 'aims to serve the academic needs of all undergraduate medical students, residents and young practising clinicians in a comprehensive manner'.It certainly does appear to cover just about all aspects of surgical practice to a greater or lesser degree. The style is relatively old fashioned and in some respects this is reflected by some content, which shows a scope of pathology which is rarely seen in the Western world. The aim of the book would appear to be to produce such a volume as cheaply as possible and in some respects that is no bad thing. However, this aspect is relatively obvious. I believe that a comprehensive surgical textbook is possibly better done elsewhere, although I suspect at a greater cost. In conclusion, I suspect this is probably the incredibly cheap comprehensive generalist's surgical textbook. I imagine, in certain areas of the world, it will be popular among its target audience, but I do not think there is a particular market for this in the UK.

Recent Advances in Surgery 5

Roshan Lall Gupta (ed). 226 × 149 mm Pp. 349. Illustrated. 1996. New Delhi: Jaypee Brothers Medical Publishers. Price not provided.

This booklet is soft-cover, lightweight and cheaply printed in India (a few words are hardly legible). Thirty-five authors (all Indian except one Japanese), from India (28), USA (3), Abu Dhabi (2), Australia and Japan (one each) contributed 21 'topics of deep interest to the postgraduate students and practising surgeons, especially such issues that are related to the clinicians in the Indian sub-continent'. The cover claims that 'this volume examines the development of multiple areas of general surgery ranging from penile revascularization, anorectal anomalies, disorders of the pancreas, problems of the GI tract ... to the management of cancer of the head and neck'

The first contribution is presented as 'a detailed chapter by the Editor reviewing recent progress in surgery encapsulates the current trends'. I found this chapter shallow in places and biased. Sixty-four of the quoted 212 references (11 from India) were published before the 1990s (a few in the 1960s) and so cannot be considered recent. Recent topical advances in molecular biology, sepsis, hepatic surgery and trauma were not mentioned, while a 'biologically engineered trachea' was discussed. Only six of the 21 chapters included material of special interest to the Indian subcontinent, such as: 'Head and neck cancers', 'Reconstructive surgery in leprosy', "'Home made' device for percutaneous gastrostomy", 'Tropical pancreatitis' (an excellent chapter), and 'Inflammatory bowel disease in India'. In the chapter entitled 'Laparoscopic surgery: its relevance to Indian urology', I could not find the 'Indian relevance', while in chapters such as 'Use of lasers in surgery' I did not find relevance even for our residents here in New York. A few chapters like 'Unusual and difficult surgical encounters on benign biliary disease' are enjoyable and very good reading The quality of reference lists varies among contributions and many key references are omitted. Not knowing much about Indian surgery I consulted our resident Dr Ramesh Paladugu who informed me of the huge market for surgical literature in the Indian subcontinent, represented by many thousands of residents and surgeons administrating Western surgery under adverse circumstances to a population of over 700 million. Dr Paladugu tells me that the 'Recent Advances in Surgery' series is very popular among residents in India, at a price of 300 rupees (about US $10) it is much more affordable than foreign books. Sections of this book represent valuable reading for residents and an update for practising surgeons At this price I would consider it a bargain.

Principles of Surgical Research. 2nd ed.

R. T. Mathie and K. M. Taylor (eds). 240 × 168 mm. Pp. 269. Illustrated. 1995. Oxford: Butterworth-Heinemann. £40.

This is an excellent small book containing a wealth of information, principally directed at a junior doctor beginning research. The book attempts to be comprehensive and is set up in four sections. Section 1, designing and starting a research project; Section 2, conducting a research project; Section 3, computing and statistics, and Section 4, how to do it. The first section has some meaty philosophical commentaries; although, as Kenneth Calman states in the foreword, the reason for doing research is often a material one in climbing the ladder, the philosophy that all good surgeons should do research seems reasonable. There are excellent chapters on information management and applying for a research grant. The section on conducting a research project contains much needed information and includes statistics, the use of animals and the ethics of research. A short introduction to molecular biology in surgical research may seem slightly inappropriate in the book, but it is well written The third section contains useful information on computing and statistics. The final section contains guidance on the presentations of papers, writing a paper, illustrating presentations and writing and submitting a thesis. Again this is highly useful information.

This reviewer would classify the volume as essential reading for any young clinician starting out on research It contains information which can be used at timely intervals during such work. Although directed at surgical researchers the book would be equally useful to those embarking on other areas of medical enquiry. Many of the technologies and, indeed, areas of research are now shared by interdisciplinary teams. Perhaps one thing that should be added in terms of advice is that when starting a project the young researcher should seek to become attached to a critical mass group with an excellent record in clinical research. This usually ensures success; going it alone can be difficult.

Churchill's Pocketbook of Surgery

A. T. Raftery. 187 × 105 mm. Pp. 485. Illustrated. 1996. Edinburgh: Churchill Livingstone. £13.50.

'What is the good of my writing a thundering big book, when everything is in this little green book so despicable for its size?'. Thus commented Charles Darwin to Thomas Henry Huxley on seeing a fourpenny pamphlet in which the essential arguments of *The Origin of Species* were summarized. *Churchill's Pocketbook of Surgery* is white, not green, but one can imagine a modern surgical Darwin repeating his famous namesake's comment. The truth is that the modern medical student prefers to buy small didactic books, not, as AT Raftery suggests, because of any impecunity, but because students like short succinct 'learning bites' as a way of coping with an ever expanding curriculum. This book admirably provides the undergraduate surgical bite.

Several pocketbooks are now available but this one must rank in the forefront of the genre. The book is sturdily made, produced in three colours and fits snugly into the pocket. It is easy to find one's way around this book with a contents list on the front cover and a good index at the back. The entire spectrum of surgery is covered and important data are highlighted in boxes and tables. The text is snappy but there are some wonderful typographical errors (e.g. carcinoma of the female disease (*sic*), reccurent (*sic*), iverticulitis (*sic*)). The medical students who have seen the book liked the tables of normal biochemical and haematological values given on the inside of the back cover but regretted the dearth of illustrations. Like most surgical books, this one is predominantly based on pathology, but an attempt is made at a symptom-based approach in some areas (e.g. acute abdomen). House surgeons and SHOs will not find this book particularly useful but medical students will devour it.

Human Anatomy. Color Atlas and Text. 3rd ed.

J. A. Gosling, P. F. Harris, J. R. Humpherson, I. Whitmore and P. L. T. Willan. 275 × 215 mm. Pp. 360. Illustrated. 1996. London: Mosby-Wolfe. £24.95.

This anatomy textbook comprises a systematic series of excellent photographs of cadaveric dissections which are accompanied by elegant explanatory diagrams. The text is succinct and exactly matches the relevant illustrations. In this edition each chapter has been supplemented with a section of multiple choice questions and a set of short clinical case histories chosen to illustrate pertinent anatomical points The nature of the book precludes consideration of some important anatomical principles, such as the segmental anatomy of the lungs and liver, and anatomical variation cannot be demonstrated when the illustrations are based on single dissections However, the authors, illustrators and photographers have been extremely successful in achieving their objective. As a manual for undergraduates or basic surgical trainees requiring practical instruction in gross anatomy, this book has much to commend it. It is a beautiful piece of work.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** In order to avoid subsequent embarrassment, authors are requested to submit with their manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that publications or submissions using the same data set should be submitted to the Editors to allow assessment of any potential overlap with the submission to the Journal. The title page should indicate whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 4101. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state whether an abstract of the work has been published and an appropriate reference should be given on the title page. Authors must disclose in the covering letter any potential or actual personal, political or financial interest they may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editor. Sources of financial support for the work should also be acknowledged. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; 308: 39–42). When a paper has many authors, they may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995, 345: 668).

Following final approval of articles, authors are asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify.** Particular attention should be taken to ensure that any articles submitted adhere **exactly** to Journal style in all respects. Please send us digital versions of your figures. Ideally, these should be sent in native format or PICT if created on a Mac, or in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential to the understanding of the figure, try to make them coarse Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; 296: 401–5 or the *Annals of Internal Medicine* 1988; 108: 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary of no more than 150 words on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal. Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation. **Randomized controlled trials** should be clearly identified as such in the title and summary.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications that may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction, methods, results and discussion These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. This should clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. It should embody the purposes of the study or investigation, basic procedures (study material, and observational and analytical methods), main findings (with specific data and their statistical significance) and the principal conclusions. The summary should be written in clear prose.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Radiographs, photomicrographs, etc should be submitted in the form of glossy prints, original transparencies or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work the original source must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; *66*: 184–6. The sequence for the chapters of a book should be. author(s); chapter title; editors; book title; place of publication; publisher: year of publication; page numbers. For example: Calenoff L, Rogers L Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *Br J Surg* 1991; 78: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of data, the *analysis* of data and the *interpretation* of results.

Design

Authors should set out clearly the objectives of the study. identify the primary and secondary hypotheses, and the chosen endpoints, and explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study The use of standard deviation and standard error should be clearly distinguished. Use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value. For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

SURGERY OF THE HAND AND UPPER EXTREMITY

A McGraw-Hill Publication

Clayton A Peimer MD, Chief of Hand Surgery, Millard Fillmore Hospitals,
Buffalo, New York, USA

496 pages, 3,000 illustrations, Hardback, 0-07-049293-X, £225.00, March 1996

This definitive new treatise covers diagnosis and surgical management of the hand as well as those procedures of the elbow and shoulder commonly performed by the hand surgeon.

Over 3,000 superb illustrations provide step-by-step guidelines of surgical procedure. Leading authority Clayton Peimer and an international team of over 120 expert contributors form a uniquely talented author team which defines the future direction of operative hand surgery. The text is logically organised and progresses proximally (shoulder) to distally (fingers) to give the reader a quick access to the material.

- **superior art programme - 1,500 line diagrams and 1,500 half-tone illustrations depict surgical technique in unprecedented fashion**
- **includes surgical procedures of the elbow and shoulder - particularly those commonly performed by the hand surgeon - no other text offers this**
- **examines common pitfalls and complications of each procedure**
- **includes differential diagnosis of each disorder**
- **reviews non-surgical management issues including anaesthesia and rehabilitation**

Journal of EVALUATION IN CLINICAL PRACTICE

Editor:
Professor Andrew Miles
Technical Editor:
Mr Nicholas Price

Assistant Editors:
Dr. Myriam Lugon
Mr. Jonathan Asbridge

The *Journal of Evaluation in Clinical Practice* aims to pioneer the development of a new discipline for the rigorous critical evaluation of clinical effectiveness, appropriateness and efficiency. The strategic vision and approach of the *Journal of Evaluation in Clinical Practice* will therefore focus clearly on the methodology of healthcare quality improvement and firmly upon the means by which outcomes can be measured in tangible, clinically-valid terms.

The Editor and the Board invite learned authors to submit articles that present and discuss findings in relation to evidence-based clinical care, its introduction into clinical practice and the measurement of the resulting clinical benefit. All aspects of medical/clinical audit and multi-centre/major clinical research which has produced evidence-based clinical guidelines will be enthusiastically considered by the Journal, provided that the essential prerequisite of academic rigour has been satisfied. All submissions will be reviewed by at least two individuals with well-recognised expertise in the area of interest of the submitted article.

Subscription Information

Journal of Evaluation in Clinical Practice is published quarterly. Subscription prices for 1996 are as follows:

	Europe	Rest of World	N America
Institutions	£143.00	£157.00	$253.00
Individuals	£65.00	£71.50	$115.00

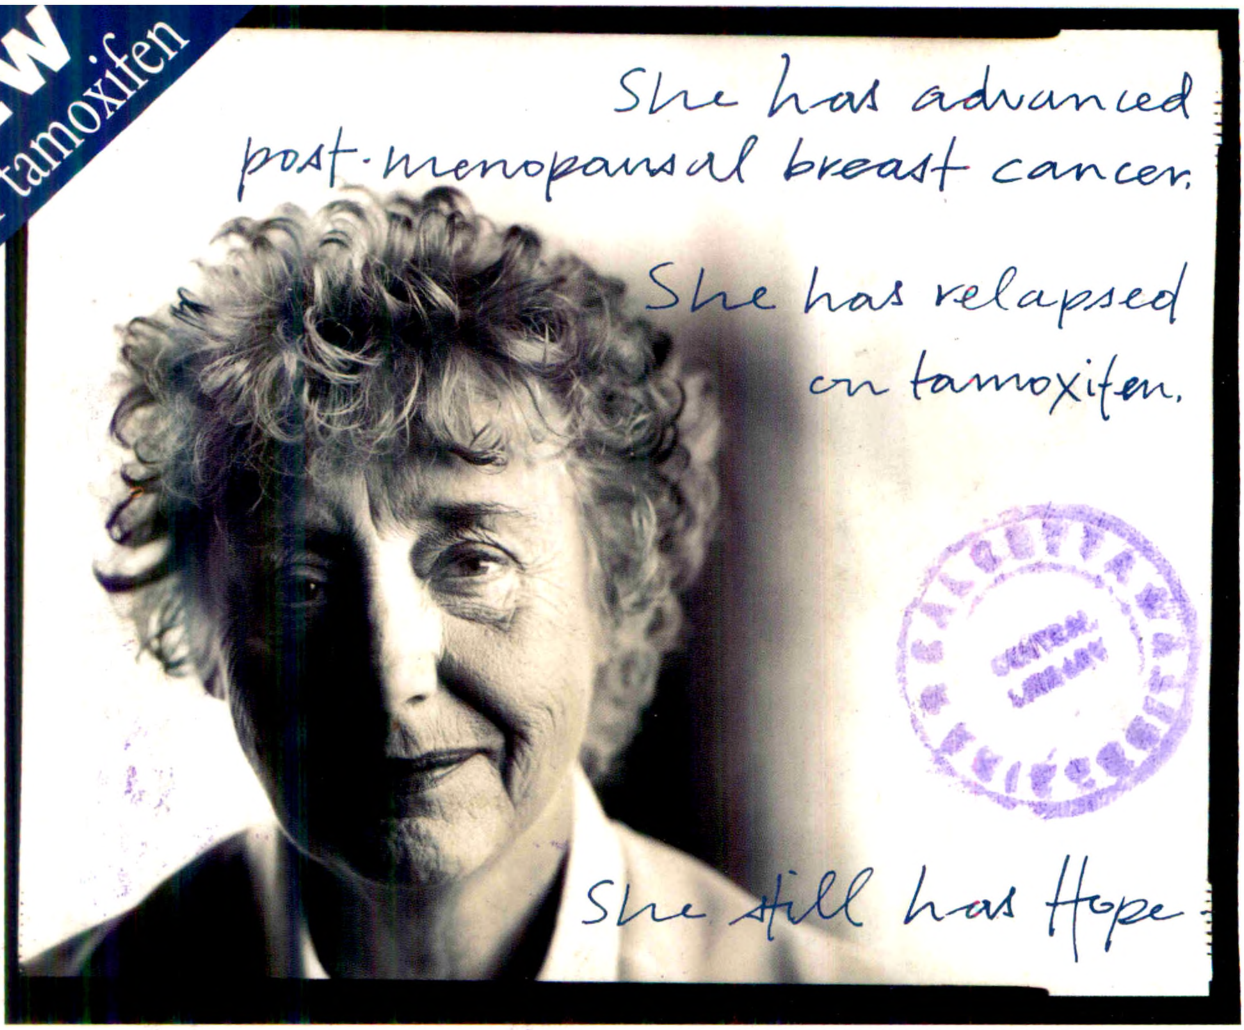
NEW

After tamoxifen



CENTRAL LIBRARY

Many of the currently available alternative hormonal therapies, that can be used after tamoxifen may have limitations in terms of tolerability and convenience. Where do you turn after tamoxifen? 'Arimidex' may offer you and your patients an alternative, new hope.

New from Zeneca Pharma, the oncology company which researched and developed tamoxifen, 'Arimidex' is the first once daily, oral, highly selective, non-steroidal aromatase inhibitor for advanced, post-menopausal breast cancer.

'Arimidex' has been shown in trials to produce a clinical benefit in over a third of patients and to be as clinically effective as megestrol acetate[1], but was associated with significantly fewer patients complaining of weight gain[1] - and significantly fewer patients on 'Arimidex' experienced a weight gain of >10%.[1] (compared to entry)

Also, as 'Arimidex' is a highly selective, non-steroidal aromatase inhibitor, there is no need for concomitant steroid replacement therapy.

And once a day convenience facilitates good patient compliance.

So when the time comes to move on from tamoxifen, because life is worth living, consider 'Arimidex'.

Arimidex ▼

anastrozole

A new hope in advanced, post-menopausal breast cancer.

'ARIMIDEX'

Prescribing Notes

Consult Data Sheet before prescribing

Special reporting to the CSM required

Use: Treatment of advanced breast cancer in post-menopausal women. Efficacy has not been demonstrated in oestrogen receptor negative patients unless they had a previous positive clinical response to tamoxifen.

Presentation: Tablets containing 1 mg of anastrozole.

Dosage and Administration: 1 mg orally once a day.

Contra-indications: Pre-menopausal, pregnant or lactating women, children, patients with severe renal impairment and patients with moderate or severe hepatic disease. Co- administration with oestrogen-containing therapies.

Precautions: Menopause should be defined biochemically where doubt about hormonal status. Care in driving or operating machinery. No data to support safety in patients with moderate or severe hepatic impairment or severe renal function impairment. No information on use in combination with other anti-cancer agents.

Undesirable events: 'Arimidex' is generally well tolerated. Pharmacologically predicted side effects include hot flushes, vaginal dryness and hair thinning. Other side effects include gastrointestinal disturbances (anorexia, nausea, vomiting, diarrhoea), asthenia, somnolence, headache or rash. Slight increases in total cholesterol. Hepatic enzyme changes, but no causal relationship established.

Legal category POM

Product licence number 12619/0106

Basic NHS cost 28 tablets £83.16

'Arimidex' is a trade mark, the property of Zeneca Limited

iratory tract infections, urinary
t infections, intra-abdominal infec-
s, skin infections, septicaemia and
microbic intra-abdominal, skin and
er respiratory tract infections;
ents with impaired host defences.
__age__ (intravenous use only):
lts/elderly/children over 12:
ally 4.5g every 8 hours (range from
-4.5g every 6-8 hours dependent
he severity). *Children:* No data to
port use. *Renal Impairment:*
ing reduction may be necessary,
se consult data sheet. __Contra-__
__cations__: Hypersensitivity to peni-
n, cephalosporin or ß-lactamase
bitors. __Warnings__: Discontinue if
phylactic or allergic reaction
urs. __Precautions__: Periodic assess-
t of renal, hepatic and haemato-
cal function advised. Discontinue
bleeding manifestations occur.
istant bacteria may cause superin-
ion. Convulsions may occur with
her than recommended doses.
sibility of hypokalaemia in patients
low potassium or on cytotoxics or
etics. Evaluate patients for
hilis prior to treatment for gonor-
ea. __Use during pregnancy or lacta-__
: Only if benefit outweighs risk.
__e-effects__: Most frequent: gastro-
stinal disturbances; various skin
ctions including rashes, erythema,
itus and urticaria; allergic reac-
s; superinfection; phlebitis, throm-
hlebitis, pain/inflammation at site
injection. Less frequent: muscle
or weakness; hallucination; dry
th; stomatitis, sweating; oedema;
dness and rarely leucopenia, inter-
ial nephritis. Haematological
nges, increases in liver and rarely
al function test values have been
orted. __Overdose__: Piperacillin may
reduced by dialysis. __Presentation__:
ocin 2.25g: Vials containing
racillin 2g (as piperacillin sodium)
tazobactam 250mg (as tazobactam
ium). Tazocin 4.5g: Vials containing
racillin 4g (as piperacillin sodium)
tazobactam 500mg (as tazobactam
ium). __Basic NHS Price__: 4.5g
ngth:- single vial £13.16, single
sion pack £14.48; 2.25g strength
le vial £7.24. __PL nos__: 4.5g strength
0095/0254; 2.25g strength PL
5/0252). __PA nos__: 4.5g vials
68/2; 4.5g combipack 37/68/3;
5g vial 37/68/1. __Legal Category__:

Wyeth Lederle

Tazocin monotherapy is as effective as combination therapy in both LRTI[1] and intra-abdominal infections,[2,3] and more cost-effective than "triple" therapy.[2]

One antibiotic is as effective as a cocktail

Choose Tazocin, and you can keep your cocktails in the cabinet.

TAZOCIN*

(piperacillin/tazobactam)

Solo power in polymicrobial infections

Production Editor: Alison Cherrie
Editorial Controller: Emma Lawrence
Editorial Assistant: Jane Barness

Advertising enquiries should be directed to: Advertising Department, Blackwell Science Ltd, Osney Mead, Oxford OX2 0EL, UK. Telephone: 01865 206 206. Facsimile: 01865 200 918.

Subscriptions. The British Journal of Surgery is published monthly by Blackwell Science Ltd. Subscription prices for 1996 are: **Institutional** £114·50 (Europe), £128·50 (Overseas), $207 (North America); **Individual** £74·50 (Europe), £84 (Overseas), $135 (North America); **Trainee** £34·50 (Europe), £39 (Overseas), $63 (North America). Subscribers in Canada must add 7% to the subscription price to allow for GST. Subscribers in Europe must quote their VAT registration number or state that they are not registered. Subscribers in the following countries who are not VAT-registered must add VAT at the appropriate rate: Belgium (6% TVA/BTW); France (2·1% TVA); Germany (7% MWST); Spain (4% IVA); The Netherlands (6% BTW). Orders for current subscriptions and back issues should be sent to Blackwell Science Ltd, Journal Subscriptions, PO Box 88, Oxford OX2 0NE, UK. Telephone: 01865 206180 or 206038; Facsimile: 01865 206219; E-mail: journals.cs@blacksci.co.uk. Information on this journal and other Blackwell Science publications is available on the Blackwell Science Homepage: http://www.blacksci.co.uk.

Reprint orders and enquiries to: Reprint Department, Blackwell Science Ltd, Osney Mead, Oxford OX2 0EL, UK. Telephone: 01865 206 206. Facsimile: 01865 721 205.

Despatch. The British Journal of Surgery is despatched within the UK by second class post, within Europe by air mail, and to other continents by various forms of air-speeded delivery. To the USA by air freight for forwarding by second class post*; to India by air freight for guaranteed local delivery, and to all other countries by accelerated surface post. Add to the cost of regular subscription £24/$36 for air mail delivery outside Europe.

A microfilm version of *The British Journal of Surgery* is available. Please contact University Microfilms Inc., 300 N. Zeeb Road, Ann Arbor, Michigan 48106, USA.

*Periodicals postage paid at Rahway, New Jersey, USA. Postmaster: send address changes to *The British Journal of Surgery*, c/o Mercury Airfreight International Inc., 2322 EF Randolph Avenue, Avenel, New Jersey 07001, USA.

NATIONAL UNIVERSITY OF SINGAPORE

DEPARTMENT OF SURGERY

Founded 1905

Applications are invited for **teaching appointments** in the **Department of Surgery**.

Founded 1905

Candidates should possess an approved basic medical degree with recognised postgraduate qualifications such as MMed (Surgery), FRCS or FRACS and evidence of completion of Advanced Surgical Training and preferably subspecialty training in any of the following fields:

General Surgery (in either Colorectal Surgery, Critical Care and Trauma Surgery or
  Hepatobiliary Pancreatic Surgery)
Cardiothoracic Surgery
Neurosurgery
Paediatric Surgery
Plastic and Reconstructive Surgery
Urological Surgery

Besides appointments on normal 3-year contracts, **visiting appointments** for one or two years may be considered.

Gross annual emoluments range as follows:

Lecturer	S$61,750 - 74,300
Senior Lecturer	S$67,940 - 138,090
Associate Professor	S$122,640 - 170,100

(STG£1.00 = S$2.13 approximately)

The commencing salary will depend on the candidate's qualifications, experience and the level of appointment offered. In addition, a 13th month Annual Allowance (of one month's salary) and an Annual Variable Component (of normally 2 months' salary) may be payable at year end, under the flexible wage system, to staff on normal contracts. The Professional Fee Scheme will be extended to appointees, as applicable.

Leave and medical benefits will be provided. Depending on the type of contract offered, other benefits may include: provident fund benefits or an end-of-contract gratuity, a settling-in allowance, subsidised housing, education allowance for up to three children to a maximum of S$16,425 per annum per child, passage assistance and baggage allowance for the transportation of personal effects to Singapore.

Staff on visiting appointments will be provided with emoluments comparable to those offered to staff on regular contracts.

Application forms and further information may be obtained from:

Only shortlisted candidates will be notified.

The British Journal of Surgery

The Journal is specially related with the Association of Surgeons of Great Britain and Ireland and the Surgical Research Society

VOLUME 83 NUMBER 10 OCTOBER 1996

Contents

Leading articles

1313 **Surgical management of gastro-oesophageal reflux disease**
A. Watson
Long-term reflux control can be achieved surgically but we need to establish which procedure is best

1316 **Magnetic resonance mammography**
P. J. Drew and J. R. T. Monson
This technique may be helpful in those for whom conventional radiographic mammography is problematic

Reviews

1319 **Thirty-five years of isolated limb perfusion for melanoma: indications and results**
B. C. Vrouenraets, O. E. Nieweg and B. B. R. Kroon
The main problem in assessing isolated limb perfusion is the lack of prospective randomized trial

1329 **Vascular complications of injecting drug misuse**
K. R. Woodburn and J. A. Murie
This increasingly common complication requires prompt treatment

1335 **Aetiology and treatment of anal fissure**
J. N. Lund and J. H. Scholefield
A common problem that causes significant morbidity in a young and otherwise healthy population

Association of Surgeons

1345 **Intestinal barrier dysfunction in clinical and experimental obstructive jaundice and its reversal by internal biliary drainage**
R. W. Parks, W. D. B. Clements, M. G. Smye, C. Pope, B. J. Rowlands and T. Diamond
Further data implicating the gut as a source of sepsis in obstructive jaundice

1350 **Influence of different collagenase solvents and timing of their delivery on porcine islet isolation**
S. A. White, H. H. Contractor, D. P. Hughes, P. R. V. Johnson, H. A. Clayton, P. R. F. Bell and N. J. M. London
Collagenase can affect islet recovery

1356 **Incidence and nature of bile duct injuries following laparoscopic cholecystectomy: an audit of 5913 cases**
M. C. Richardson, G. Bell, G. M. Fullarton and the West of Scotland Laparoscopic Cholecystectomy Audit Group
The learning curve is prolonged, but major duct injuries are becoming less frequent

1361 **Day-case laparoscopic hernia repair**
D. S. Evans, P. Ghaneh and I. M. Khan
Achieved in 98 per cent of patients in whom it was attempted

1364 **General surgery with a special interest in vascular surgery: changing patterns of workload**
M. S. Whiteley, S. B. Ray-Chaudhuri, J. Cornes, J. A. Michaels and R. B. Galland
Specialization in vascular surgery seems inevitable: the demise of 'general' surgery may occur in tandem

1367 **Changing patterns in aortoiliac reconstruction: a 7-year audit**
M. S. Whiteley, S. B. Ray-Chaudhuri and R. B. Galland
Aortobifemoral grafting is out, angioplasty and extra-anatomic grafting is in

1370 **Prospective study of carotid endarterectomy and contralateral carotid occlusion**
A. F. da Silva, P. McCollum, T. Szymanska and L. de Cossart
Not as high-risk surgery as was thought

1373 **Carotid endarterectomy: an underutilized means of stroke prevention (short note)**
C. D. Irvine, A. H. Davies, P. M. Lamont and R. N. Baird
The case is made for increasing the number of operations: this implies a substantial increase in funding

Association of Surgeons (continued)

1375 **Vein morphology and bypass graft stenosis**
K. Varty, K. Porter, P. R. F. Bell and N. J. M. London
Pre-existing vein wall thickening may not be related to the development of vein graft stenosis

1380 **Colour duplex ultrasonography in the rational management of chronic venous leg ulcers**
A. J. Grabs, M. C. Wakely, I. Nyamekye, A. S. K. Ghauri and K. R. Poskitt
In this study of ulcers in a community clinic, half had isolated superficial venous disease potentially curable by surgery

1383 **New graft design to inhibit myointimal hyperplasia in small vessel anastomoses** (surgical workshop)
J. A. Brennan, M. A. Enzler, A. da Silva, T. V. How and P. L. Harris
An expanded distal end may confer benefit

1384 **Exclusion from day surgery: a 1-year clinical audit** (short note)
S. K. Clark, J. P. Grieve and P. E. M. Jarrett
Some simple measures are suggested to prevent inappropriate booking for day-case surgery

1386 **A 4-year prospective audit of the cause of death after infrarenal aortic aneurysm surgery**
A. J. P. Sandison, Y. Panayiotopoulos, R. C. Edmondson, M. R. Tyrrell and P. R. Taylor
Multiple organ failure and colonic ischaemia accounted for almost half the mortality

1390 **Management cost of acute limb ischaemia**
B. D. Braithwaite, L. Jones, B. P. Heather, P. A. Birch and J. J. Earnshaw
For successful and uneventful primary treatment the costs are similar for surgery and thrombolysis

1394 **Still missing the boat with fatal pulmonary embolism**
T. E. Gillies, C. V. Ruckley and S. J. Nixon
Don't forget antithrombotic prophylaxis for patients admitted as an emergency, patients managed without surgery and those in a moderate-risk group

1396 **Prospective evaluation of dynamic contrast enhanced magnetic resonance imaging in the evaluation of fistula *in ano***
I. J. Beckingham, J. A. Spencer, J. Ward, G. W. Dyke, C. Adams and N. S. Ambrose
A study which supports dynamic MRI to identify complex fistula *in ano* more accurately than a single surgical digit, although without statistical significance

1399 **Role of the nurse endoscopist in colorectal practice** (short note)
V. Moshakis, R. Ruban and G. Wood
A nurse endoscopist can perform as well as an experienced surgeon

1400 **Disruption of the internal anal sphincter can occur after transanal stapling** (short note)
R. Farouk, P. J. Drew, G. S. Duthie, P. W. R. Lee and J. R. T. Monson
Large staplers may cause internal sphincter injuries

1401 **Disconnection, pouch revision and reconnection of the ileal pouch–anal anastomosis**
P. M. Sagar, R. R. Dozois, B. G. Wolff and K. A. Kelly
Revision of problem pouches may be helpful

1406 **Low malignant potential of the double-stapled ileal pouch–anal anastomosis** (short note)
P. N. Haray, B. Amarnath, E. G. Weiss, J. J. Nogueras and S. D. Wexner
Earlier results confirmed with long follow-up

1407 **Sequential systemic platelet-activating factor and interleukin 8 primes neutrophils in patients with trauma at risk of multiple organ failure**
A. J. Botha, F. A. Moore, E. E. Moore, V. M. Peterson, C. C. Silliman and A. W. Goode
Further evidence that neutrophil activation occurs after major injury and that serum IL-8 may predict multiorgan failure in such patients

1413 **Conservative management of infective mastitis and breast abscesses after ultrasonographic assessment**
R. J. O'Hara, S. P. L. Dexter and J. N. Fox
Ultrasonographic imaging aids conservative management of breast abscesses

Association of Surgeons (continued)

1415 **Image-guided core biopsy in patients with breast disease**
M. J. B. Chare, C. I. Flowers, C. J. O'Brien and A. Dawson
A useful test in the breast clinic

1417 **Use of covered expandable metal stents in the treatment of oesophageal carcinoma and tracheo-oesophageal fistula**
T. A. Cook and T. C. B. Dehn
This device offers a safe, effective and possibly cost-effective means of palliation

1419 **Port-site metastases in patients undergoing laparoscopy for gastrointestinal malignancy**
T. A. Cook and T. C. B. Dehn
The role of laparoscopy in staging and treatment of gastrointestinal cancer may be questioned if the tumour has breached the serosa

1421 **Radical lymphadenectomy in the management of early gastric cancer**
N. Hayes, D. Karat, D. J. Scott, S. A. Raimes and S. M. Griffin
As with a number of Japanese studies, early gastric cancer in UK patients is associated with a high incidence of lymph node metastasis, thus justifying the use of radical lymphadenectomy in their patients

1424 **Accuracy of laparoscopic ultrasonography in the staging of upper gastrointestinal malignancy**
D. N. Anderson, S. Campbell and K. G. M. Park
Sounds like a useful technique

1429 **Oesophagogastrectomy for iatrogenic perforation of oesophageal and cardia carcinoma**
D. J. Adam, A. M. Thompson, W. S. Walker and E. W. J. Cameron
Early surgery after iatrogenic oesophageal perforation in patients with oesophageal or oesophago-gastric cancer may be associated with better long-term survival

Original articles

1433 **Proximal pancreatoduodenectomy for chronic pancreatitis**
G. N. Stapleton and R. C. N. Williamson
The procedure effectively palliates pain in 80 per cent of patients

1441 **Angled metal cholangiography cannula for laparoscopic cholecystectomy** (surgical workshop)
N. D. Karanjia, D. Banerjee and G. H. Dickson
A new slant on an old technique

1442 **Hepatobiliary anatomy in patients with transposition of the gallbladder: implications for safe laparoscopic cholecystectomy**
M. Idu, J. Jakimowicz, A. Iuppa and A. Cuschieri
Beware this anomaly

1444 **Angiogenesis inhibitor TNP-470 prevents implanted liver metastases after partial hepatectomy in an experimental model without impairing wound healing**
H. Tanaka, H. Taniguchi, T. Mugitani, Y. Koishi, M. Masuyama, H. Koyama, M. Hoshima and T. Takahashi
The title says it all

1448 **Cardiac complications after hepatic resection**
K. Yanaga, K. Takenaka, K. Yamamoto, T. Nishizaki, K. Shirabe, M. Shimada, N. Kawahara, A. Chisaki and K. Sugimachi
Cardiac patients have a higher risk of cardiac and non-cardiac complications

1452 **Pilonidal sinus: experience with the Karydakis flap**
P. R. B. Kitchen
There is a low recurrence rate in this large single-surgeon series

1456 **Brush cytology for the diagnosis of rectal carcinoma**
R. Farouk, J. Edwards, M. Thorne, W. Young, A. W. MacDonald, J. R. T. Monson and P. W. R. Lee
Brush cytology can increase the diagnostic yield of rectal biopsy

1458 **Subcutaneous bridge support for defunctioning loop colostomy** (surgical workshop)
S. W. Atkinson and P. G. Bentley
A neat technique for supporting a loop colostomy

Contents

Original articles (continued)

1459 **Effect of different infusion regimens on colonic motility and efficacy of colostomy irrigation**
J. M. Gattuso, M. A. Kamm, C. Myers, B. Saunders and A. Roy
This study provides practical guidelines as to the volume and duration of stoma irrigation in patients with colostomy evacuation difficulties

1463 **Strengths and weaknesses of laparoscopic and open mesh inguinal hernia repair: a randomized controlled experimental study**
L. F. Horgan, J. C. Shelton, D. C. O'Riordan, D. P. Moore, M. C. Winslet and B. R. Davidson
This experimental study describes a useful model to assess inguinal hernia repair

1467 **A new way to prevent leakage of glycine during endoscopic transanal resection of rectal lesions** (surgical workshop)
F. Abbasakoor and R. B. Stephens
Innovative adaptation of an endotracheal tube

1468 **Effects of vertical-banded gastroplasty on bone and mineral metabolism in obese patients**
T. Cundy, M. C. Evans, R. G. Kay, M. Dowman, D. Wattie and I. R. Reid
Bariatric surgery has minor effects on bone density

1473 **Selective approach to the treatment of oesophageal cancer**
T. Junginger and P. Dutkowski
Radical node dissection may help those who can tolerate it

1477 **Erratum**

1478 **Correspondence**

1485 **Book reviews**

1486 **Notices and announcements**

1487 **Instructions to authors**

HIGHER SURGICAL TRAINING AND CONTINUING MEDICAL EDUCATION COURSES

OCTOBER 1996 - FEBRUARY 1997

Title	Level	Fee
Foundation Course on Locking Nailing 8 - 10 October 1996	HST	£395
Cancer Genetics for Surgeons 29 October 1996	HST/CME	£125
Surgical Clinical Directors Course 17 January 1997	CME	£150
Management of Breast Disease 10 - 14 February 1997	HST	*tba*
Advanced Anastomotic Techniques 11 - 14 February 1997	HST	*tba*
Training the Trainers 16 - 17 & 23 - 24 January, 17 - 18 & 19 - 20 February 1997	CME	£350
Do You Use Sedation Safely? February 1997 - *date to be confirmed*	BST/HST/CME	£135
STOP PRESS! Knee Replacement Course 11 March 1997	HST	*tba*
Surgical Workshops using Anatomical Prosection		
Rectal Cancer: Surgery and Histopathology 4 - 5 November 1996 *tbc*	CME	*tba*
Surgical Anatomy of Foot and Ankle 20 - 21 November 1996 *tbc*	HST/CME	*tba*
Cervical Spine Stabilisation for Deformity and Tumours 2 - 4 December 1996	CME	*tba*
Approaches to the Anterior Cruciate Ligament and Meniscal Suturing 13 - 14 & 16 - 17 January 1997	HST/CME	£500/£600
Surgery of the Shoulder February 1997 - *date to be confirmed*	CME	*tba*
Minimal Access Therapy Training Unit#		
Advanced Principles of Electrosurgery 4 October 1996	HST	£200
Intermediate Techniques in Arthroscopic Surgery 24 - 25 October 1996	BST/HST	£450
Laparoscopic Cholecystectomy 30 - 31 October, 6 - 7 November, 3 - 4 December 1996, 4 - 5 February 1997	BST/HST	£480-1996 £490-1997
Endoscopic Sinus Surgery 12 November 1996	HST/CME	£340
Facial Aesthetic Surgery: Endoscopic & Open Techniques* 14 November 1996	HST	£1460
Laparoscopic Rectopexy 21 - 22 January 1997	HST/CME	£645
Advanced Endoscopic Suturing Techniques 11 - 12 February 1997	HST/CME	£600

The College is currently developing a range of CME courses to be available in 1997, including I.T., Nutrition, and Surgery and the Law. Please contact Jacqui Dyson or Belinda Lowe on tel: 0171-973 2104 for more details.
# The Minimal Access Therapy Training Unit also runs a programme of courses aimed at basic surgical trainees, and is developing a programme of thoracics courses (including cardiothoracics and spinal) for late 1996/early 1997. Please contact Jane Weller on tel: 0171-973 2110 or Liz Woods on tel: 0171-312 6676 for more details.
* Facial Aesthetic Surgery is a 4-day course. The first day is held at the College, the second and third at the University of Liege, Belgium, and the fourth at the Wellington Hospital, London.
Key: BST Basic Surgical Training: HST Higher Surgical Training; CME Continuing Medical Education; *tba* to be announced; *tbc* to be confirmed.

ABRIDGED PRESCRIBING INFORMATION
CIPROXIN® INFUSION/TABLETS
(Refer to data sheet before prescribing)

Presentation ***Infusion*** Clear, almost colourless solution containing the equivalent of 100mg ciprofloxacin in 50ml, 200mg ciprofloxacin in 100ml and 400mg ciprofloxacin in 200ml solution. ***Tablets*** White tablets containing the equivalent of either 250mg, 500mg or 750mg ciprofloxacin. **Uses** Ciprofloxacin is indicated for the treatment of single or mixed infections caused by susceptible organisms. It may be used alone, pending sensitivity results, or in combination. Refer to data sheet for microbiological activity. Also indicated for prophylaxis against infection in elective upper gastro-intestinal surgery and endoscopy where there is an increased risk of infection. **Dosage and administration** ***Adults*** *Ciproxin Infusion* 100-400mg administered intravenously over 30 to 60 minutes twice daily. The 400mg dose should be administered over a period of 60 minutes. *Ciproxin Tablets* should be swallowed whole with liquid; the dosage range for adults is 250-750mg twice daily. In surgical prophylaxis, a single 750mg tablet administered 60-90 minutes before the procedure (but see interactions with oral premedicants). ***Renal impairment*** Dosage adjustment not usually required except in severe renal impairment. Reduce total daily dose by half, or adjust dose on basis of drug serum levels. ***Elderly and hepatic impairment*** No dose adjustment. ***Adolescents and children*** Not recommended. However, where potential benefit outweighs the risk, a dose of 5-10mg/kg/day (intravenous) or 7.5-15mg/kg/day (oral) in two divided doses should be used. ***Duration of treatment*** For acute infections, the usual treatment period is 5 to 7 days (intravenous) or 5 to 10 days (oral), except in cases of acute uncomplicated cystitis where treatment is 250mg twice daily for 3 days (oral). Generally, in acute and chronic infections where sensitivity is proven, treatment should be continued for at least 3 days after the signs and symptoms of infection have disappeared. **Contra-indications** Hypersensitivity to ciprofloxacin or other quinolones; also in children and growing adolescents except where the benefits of treatment outweigh the risks. **Warnings and precautions** Use with caution in epileptics and patients with a history of CNS disorders. Treatment could result in impairment of the ability to drive or operate machinery. Crystalluria has been reported, so patients should be well hydrated and excessive urine alkalinity avoided. As haemolytic reactions with ciprofloxacin are possible in patients with latent and actual defects in glucose-6-phosphate dehydrogenase activity, use with caution. **Drug interactions** Increased plasma levels of theophylline have been observed following concurrent administration with ciprofloxacin. The dose of theophylline should be reduced and plasma levels of theophylline monitored. Where monitoring of plasma levels is not possible, avoid the use of ciprofloxacin in patients receiving theophylline. Particular caution is advised in those patients with convulsive disorders. Interactions have also been noted with anti-coagulants and cyclosporin. High doses of quinolones have shown an interaction with NSAIDs in animals leading to convulsions. Administration of quinolones and glibenclamide simultaneously can potentiate the effect of glibenclamide, resulting in hypoglycaemia. Concomitant use with probenecid reduces the renal clearance of ciprofloxacin, resulting in increased quinolone plasma levels. Opiate premedicants or regional anaesthetic agents must not be administered concomitantly with ciprofloxacin when used for surgical prophylaxis. Cirproxin Tablets should not be administered within 4 hours of medications containing magnesium, aluminium or iron salts. **Use in pregnancy and lactation** Not recommended. **Side-effects** Gastro-intestinal, CNS, hypersensitivity/skin reactions, musculoskeletal and special sense disturbances. Renal and hepatic disturbances. Effects on haematological parameters. Also reported: vasculitis, pseudomembranous colitis, Stevens-Johnson Syndrome, Lyell Syndrome, haemolytic anaemia, granulocytopenia, intracranial hypertension, petechiae, haemorrhagic bullae, tenosynovitis and tachycardia. Local irritation at the site of injection (infusion only). **Overdosage** Serum levels of ciprofloxacin are reduced by dialysis. **Pharmaceutical precautions** Unless compatibility is proven, the infusion should always be administered separately. Do not refrigerate Ciproxin Infusion. **Legal category** POM. **Package quantities** *Ciproxin Infusion* bottles of 50, 100 or 200ml. *Ciproxin Tablets* Blister strips of 10 in packs of 10, 20, and 100. Product licence numbers PL 0010/0150 Infusion. PL 0010/0146-0148 Tablets. **Basic NHS cost** 250mg x 10 tablets £7.50, 500mg x 10 tablets £13.75, 750mg x 10 tablets £20.00. 100mg Infusion £10.18, 200mg Infusion £19.85, 400mg Infusion £29.00. **Date of preparation** August 1994.

Cuschieri Courses in Minimal Access Therapy

SURGICAL SKILLS UNIT

Professor A Cuschieri : Director (MATTUS), Director of Surgical Skills Unit

The Surgical Skills Unit offers

- lab based skill courses
- simulated models on animal tissue
- experienced tutors
- live theatre demonstrations
- intensely practical programmes
- small group format
- MATTUS approved courses

Advanced Endoscopic Surgery- a 5 day lab based practical course for experienced endoscopic surgeons covering advanced skills such as endoscopic suturing techniques and internal and external knot tying. Endorsed by SAGES. Fee £1200.

Essentials of Laparoscopic Surgery - a 3 day lab based practical course covering the essential skills and safety procedures for basic laparoscopic operations. Recommended by E.A.E.S. Fee £550. (extended 5 day course also available).

Practical Aspects of Laparoscopic Fundoplication - a 3 day lab based practical course covering the practical and clinical aspects of both partial and total laparoscopic fundoplication. Fee £950.

Laparoscopic Colorectal Course - a 3 day lab based course for experienced laparoscopic surgeons aimed at giving the skills and confidence to develop clinically based colorectal laparoscopic surgery. Fee £900.

Laparoscopic Exploration of Common Bile Duct - a 3 day lab based course on single stage management of choledocholithiasis at the time of laparoscopic cholecystectomy. Covers skills of cannulation of CBD, choledochoscopy, stone extraction and suturing. Fee £850.

Thorascopic Sympathectomy- a lab based course which includes didactic sessions on the anatomy of the autonomic nerves, indications, instrumentation, safe access, anaesthetic implications and conduct of sympathectomy.

Other Specialist Course are available in Surgical Skills Unit.

HEALTHWORKS MEDICAL INFORMATION SERVICES &
PRODUCTS LOOK AT OUR INTERNET SITE AT:
http://www.healthworks.co.uk

Healthworks now offers access to MEDLINE, the largest database of published medical literature. It is exceptionally easy to use and it is offered at an affordable price.

- ***No hourly database charges - £35 per month for unlimited use***
- ***Relevancy ranking of search results***
- ***Document delivery interface - point and click for full text copies***
- ***Online editing of search results***
- ***Easy searching with natural language commands***
- ***Advanced Boolean searching options***
- ***No CD Rom equipment required, no concerns about lost, stolen or damaged disks, no delay receiving up-dates***
- ***Portable - you take your personal access code with you this can be used from any desktop***

Why is it so inexpensive? Advanced Internet delivery techniques allow this service to run at such a reasonable rate. For a free test drive of Medline on the Internet point your browser to http://www.healthworks.co.uk

Single User £35 per month **2 - 10 Users £30** per month **10 + Users £25** per month

2nd INTERNATIONAL GASTRIC CANCER CONGRESS
of the
INTERNATIONAL GASTRIC CANCER ASSOCIATION (IGCA)

April 27-30, 1997
Klinikum rechts der Isar
Department of Surgery
Technische Universität München, GERMANY

President of the IGCA: M. Nishi, M.D.
Congress President: J. Rüdiger Siewert, M.D., FACS
Congress Secretary: Jürgen D. Roder, M.D.

Topics

- New prognostic factors
- Molecular biology and pathology
- Modern staging of gastric cancer
- Multimodal treatment – problem of response
- Is there a place for postoperative chemotherapy?
- Gene-therapy: new horizons?
- Lymphadenectomy: closing remarks
- Surgical treatment: state of the art
- Quality of life after gastrectomy
- Gastric lymphoma: eradication or gastrectomy?
- Palliative treatment of gastric malignancies
- Intraoperative additive therapy
- Future studies for gastric cancer

Consensus Conference
(IGCA/ISDE)

- Classification and treatment of adenocarcinoma of the esophagogastric junction

THE CHOICE FOR QUALITY WORLDWIDE

With a reputation built on consistently high quality standards, Swann-Morton Ltd is a leading manufacturer of surgical blades and scalpels to the world's surgeons.

Additional to the company's comprehensive surgical ranges are the 'Major' Orthopaedic range, the 'Fine' range, 'Minor' disposable scalpels, and specialised blades such as myringotomy and cervical biopsy. All ranges are subject to constant product development in response to customer demand. All appropriate products are sterilised by Swann-Morton (Services) Ltd.

As well as achieving BS5750, subsequently updated to BS EN ISO 9001, Swann-Morton have now been accredited to EN 46001, which enables them to CE mark their products under the Medical Device Directive (93/42/EEC).

THE AUSTRALIAN AND NEW ZEALAND JOURNAL OF SURGERY

Chairman &
Editor in Chief
G. J. A. Clunie

ISSN 0004-8682
Published monthly

Editors
J. Ludbrook
I. B. Faris

The Australian and New Zealand Journal of Surgery, established for over 60 years, is the leading surgical journal published in Australia, New Zealand and the Asia-Pacific region. Published on behalf of the Royal Australasian College of Surgeons, the journal promotes outstanding surgical practice and research of contemporary and international interest.

High quality papers concerning all fields of surgery and its related disciplines are published. A programme of continuing education for surgeons at all levels is also provided as well as the occasional historical discussion. A comment and reply section encourages lively discussion on previously published articles. Comprehensive book reviews and a monthly meetings update also feature.

The Australian and New Zealand Journal of Surgery is indexed in *ADONIS, Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Info-Med, University Microfilms, CAB International, Scisearch, Current Clinical Cancer* and *Research Alert.*

The Australian and New Zealand Journal of Surgery is published monthly. The subscription rates for 1995 (Volume 65) Aus$276.00 (Australasia), US$392.00 and Aus$560.00 (elsewhere). The Journal is dispatched to subscribers outside Australasia by surface air-lifted post.

Surgical management of gastro-oesophageal reflux disease

The past decade has seen important developments in the management of gastro-oesophageal reflux disease (GORD). The emergence of powerful antisecretory drugs has increased the proportion of patients whose oesophagitis can be healed to around 90 per cent, which some predicted would sound a death knell for antireflux surgery. However, there have been equally exciting surgical developments, arising from greater understanding of the mode of action of antireflux procedures and the genesis of mechanical complications, and, more recently, the adaptation of several antireflux procedures to a laparoscopic approach.

Although GORD is a common disorder affecting up to 40 per cent of the population, the majority have mild disease, resulting from transient relaxation of a normal lower oesophageal sphincter (LOS); this can be controlled effectively with lifestyle changes and appropriate pharmacological treatment. A minority have more severe disease, with ulcerative, circumferential oesophagitis, often associated with severe impairment of the LOS and peristaltic function, and a tendency to develop complications such as ulcer, stricture and Barrett's columnar-lined oesophagus (CLO); 44 per cent of these patients will have unhealed oesophagitis after 2 months of treatment with omeprazole 40 mg daily[1]. GORD is a lifelong condition and, of those who can be healed, over 80 per cent relapse when treatment is stopped; even if omeprazole is continued in therapeutic dosage, up to 30 per cent relapse by 1 year. The desirability of lifelong virtual anacidity, particularly in young patients, is questionable, even though serious consequences of hypergastrinaemia and altered bacterial colonization are theoretical or confined to animal studies. A recent randomized controlled trial showed antireflux surgery to be superior to long-term therapy with H_2-receptor antagonists[2].

Failure of medical treatment is the principal indication for antireflux surgery and may encompass incomplete control of symptoms, persistent oesophagitis or frequent relapses. Reduced likelihood of success may be signalled clinically if regurgitation is a predominant feature, particularly if associated with laryngeal or respiratory symptoms, endoscopically if circumferential erosive oesophagitis is present and functionally if there is evidence of LOS failure or a significant alkaline component to the refluxate. Antireflux surgery should be discussed with young, fit patients who can only be maintained in remission on long-term antisecretory drugs; increasingly, patient preference is an indication for surgery. Complications of GORD, such as ulcer, stricture and Barrett's CLO, while associated with the most severe pathophysiological disturbances, are not absolute indications for operation, although many would favour surgery in younger patients. Controlled studies of Barrett's CLO have shown that antireflux surgery promotes greater healing of stricture than acid suppression, arrests progression of columnarization in a higher proportion of patients and promotes regression in a minority[3]. However, there is no current evidence to demonstrate that antireflux surgery can prevent adenocarcinoma.

Of the available operations, the 'floppy' Nissen fundoplication is the most popular, resulting in symptomatic and objective control of reflux in 91 and 83 per cent of patients respectively[4]. There have been several modifications of the original technique, designed to reduce the incidence of mechanical complications, principally slippage, disruption, dysphagia, gas bloat and inability to belch or vomit. These have included performing a short wrap 1–2 cm in length over a 50–60-Fr bougie, the addition of a crural sling repair and division of the short gastric vessels. These modifications have reduced the incidence of troublesome dysphagia to 3 per cent, but the incidence of gas bloat remains at 11 per cent and that of inability to belch or vomit is considerably higher[4]. These problems are believed to relate to the creation of a supracompetent LOS which relaxes imperfectly[5].

Concern about these issues has resulted in a revival of interest in partial fundoplication procedures, which were previously believed to offer inferior reflux control. The 'physiological' antireflux procedure described by Watson and colleagues[6] is predicated on the hypothesis that correction and accentuation of the factors known to contribute to the valvuloplasty component of competence (the crural sling, angle of His and length of intra-abdominal oesophagus) may enable reflux control without total fundoplication and, by maintaining LOS relaxation, may reduce the incidence of mechanical complications. The hypothesis has been confirmed with subjective and objective reflux control equalling the best reported results of Nissen fundoplication, but with virtual abolition of mechanical complications, findings which have been confirmed by others. The Lind and the Toupet partial fundoplication procedures have been compared in three randomized controlled trials with a 'floppy' Nissen fundoplication, with equivalent subjective and objective reflux control being demonstrated. However, mechanical complications were more troublesome with the Nissen procedure, persisting at late assessment up to 5 years in two studies[7,8]. There has recently been an increased deployment of partial fundoplication procedures, particularly among advocates of the 'tailored' approach to antireflux surgery; patients with manometrically normal oesophageal body motility undergo a 'floppy' Nissen procedure and those with significant peristaltic impairment, felt to be at greatest risk of developing complications with a total wrap, undergo a partial fundoplication[9]. That such an approach has not compromised the degree of reflux control is further support for the efficacy of currently used partial fundoplication procedures, as patients with significant peristaltic impairment are known to be the most severe refluxers[10].

Undoubtedly, the most exciting development in antireflux surgery has been the introduction of laparoscopic fundoplication and the demonstration that, at least in the short term, similar subjective and objective results to the open approach can be achieved with most of the commonly used procedures, but with more rapid recovery. However, there is some evidence that the incidence of mechanical complications and impaired LOS relaxation may be higher after laparoscopic Nissen fundoplication than with the open approach[11]. Some 6000 cases of various types of laparoscopic fundoplication have now been reported worldwide, with an overall success rate of 90 per cent, a mortality rate less than 0·5 per cent but with a morbidity rate between 5 and 10 per cent. Rather disturbingly, oesophageal and gastric injury has featured prominently in reported morbidity and mortality, emphasizing the necessary prerequisites of experience in oesophageal surgery and supervised training in laparoscopic fundoplication. The majority of patients are suitable for a laparoscopic approach, although difficulty may be encountered in the very obese and in those with transmural oesophageal inflammation. Providing the early results of laparoscopic fundoplication are continued into the long term, it will offer an attractive and cost-effective alternative to lifelong medication, particularly for young patients. However, any relative advantage must be assessed by randomized controlled trials encompassing cost and quality of life measurement in addition to the more traditional endpoints.

In 1996, effective, long-term reflux control can be achieved by antireflux surgery in expert hands and this is more likely to be operator than procedure dependent. There is a strong case for concentrating antireflux surgery in centres where expertise is strong, and where there is a sufficient throughput of patients and facilities for oesophageal measurement, relevant both to preoperative assessment and quality control of results. The remaining area with potential for further improvement is the elimination, as far as possible, of the small but definite incidence of troublesome mechanical complications which is probably more procedure than operator dependent. If we are to gain the support of our gastroenterological colleagues in mounting randomized controlled trials of optimal medical therapy *versus* laparoscopic fundoplication, we should be prepared to establish, by similar means, which procedure provides the best combination of effective reflux control, avoidance of mechanical complications and improved overall quality of life.

Magnetic resonance mammography

Recent technical advance in magnetic resonance imaging (MRI) has facilitated the development of magnetic resonance mammography (MRM) as a new breast imaging modality that offers significant potential advantages over conventional radiographic mammography. While the role of conventional mammography has long been established for both screening and assessment of palpable lesions, there are certain groups of patients for whom this technique has inherent disadvantages. Previous surgery to the breast causes parenchymal scarring, which may prevent detection of malignant lesions, and mammographically dense breasts, found particularly in younger women, may obscure an underlying malignancy. In these younger patients susceptibility to radiation-induced breast cancer is also a definite concern. For these groups in particular MRM offers a potentially significant clinical advantage.

Some of the earliest studies of the diagnostic applications of MRI were performed on patients with breast cancer[1]. However, the results proved disappointing, with MRI faring no better than conventional mammography in delineating malignant lesions[2]. This was principally because of the relatively poor image quality achieved with whole body coils and the inability of MRM to detect microcalcification. Subsequently, advances in scanning techniques and the development of specialized breast coils have allowed the evolution of MRM as a clinically useful investigation.

In brief, the signal required for the generation of an image is produced when hydrogen nuclei, previously aligned in a magnetic field and excited to a higher energy state by the input of electromagnetic radiation (radiowaves), relax back into their resting state. Several magnetic fields are used to provide spatial information and a Fourier transform is used to convert the electromagnetic signal into the image. By varying the length of time before repeating the input of energy or reading the resultant signal, the various T1 and T2 images can be produced. In general, fat is bright on T1 images and water is bright on T2 images. Contrast enhancement became available with the introduction of gadolinium-based contrast agents in the mid 1980s[3]. Chelating the gadolinium to diethylenetriamine penta-acetic acid (DTPA) reduced toxicity while improving osmolarity and water solubility. The normally hyperintense signal produced by the fat within the breast can now be suppressed, which improves the clarity of the image and facilitates the use of such contrast agents[4].

Early studies of simple MRM before and after contrast enhancement demonstrated a markedly increased sensitivity for the detection of breast cancer, although this increase in sensitivity was offset by an associated drop in specificity as some benign lesions, such as fibroadenomas, also enhanced after contrast[3]. Fast scanning techniques were subsequently developed with somewhat amusing acronyms, such as turbo FLASH (fast low-angle shot). These techniques allowed dynamic MRM which employed an analysis of the speed and pattern of enhancement to provide the diagnosis. Benign lesions tend to enhance relatively slowly and homogeneously, while malignant lesions enhance rapidly and heterogeneously[5].

The proponents of simple scanning before and after contrast enhancement have highlighted the problems associated with selection of regions of interest when interpreting dynamic scans[6]. However, recent developments in dynamic scanning have facilitated analysis of the whole tumour rather than specific regions of interest. With these techniques specificities of up to 98 per cent may be achieved, with the sensitivity remaining at around 86 per cent[7].

Today, a full range of diagnostic procedures can be performed using MRM[8]. There are now non-ferromagnetic needles and biopsy guns available for magnetic resonance-guided fine-needle aspiration cytology, core biopsy and preoperative mark up of lesions which are visible only on MRM. In the last of these, however, a radiograph of the lesion after excision cannot be used to ensure that the correct tissue has been removed; a further MRM is required at a later stage for such confirmation.

MRM should provide considerably more diagnostic information than conventional mammography. The scar tissue associated with local breast surgery does not usually enhance significantly with Gd-DTPA and this facilitates the early detection of recurrent cancer[4]. In addition, radiographically dense breasts do not represent a problem for MRM diagnosis because of the fundamentally different method of image acquisition of the latter technique. There is usually no need for the breast to be compressed during MRM unless an interventional procedure is planned and the patient can lie in a comfortable prone position with the breast hanging down within the breast coil. No physical discomfort should be experienced and the only significant psychological problem encountered is that patients with claustrophobia cannot enter the confines of the scanning tube. As there is no ionizing radiation associated with MRM, multiple scans are safe. Also, unlike the iodinated contrast media used in many radiographic examinations, Gd-DTPA causes reactions only extremely rarely and sensitization is not considered to be a significant problem. However, the usual contraindications for MRI still apply.

While more diagnostic information may be gleaned from MRM, such information takes a long time to accumulate and does not come cheap. A routine dynamic scan normally takes between 30 and 40 min, and for interventional magnetic resonance techniques the procedure time may stretch to over an hour. No major alterations to the MRI scanner are required to perform MRM but there are extra costs involved in purchasing the breast coils, interventional equipment and the software required for the specialized scan sequences. Once generated, the basic scans can be interpreted easily, although the more complex analysis of dynamic MRM requires computer technology unavailable outside specialist centres. Even when the capital outlay for the scanner has been met, the cost of basic MRM with and without contrast enhancement alone is still approximately 20 times that of conventional mammography.

MRM will not replace radiographic mammography as a first line investigation because of its greater costs and the restricted availability of suitably equipped scanners. However, evidence suggests that this scanning technique should be used for patients in whom traditional mammography is unhelpful or potentially harmful[9]. This includes young women with a significant genetic risk, those with breast prostheses, those at high risk of recurrent cancer following breast conserving therapy and women for whom the traditional mammogram is equivocal. MRM now offers the reassuring prospect of sensitive and specific breast imaging for these patients, without the risk of exposure to repeated doses of ionizing radiation.

Thirty-five years of isolated limb perfusion for melanoma: indications and results

Isolated limb perfusion (ILP) for limb melanoma remains controversial despite its frequent use for over 35 years. To determine whether it has proven benefits, reported results have been reviewed. The value of adjuvant ILP cannot be determined from the multitude of retrospective studies on this subject. Preliminary results of the large European Organization for Research and Treatment of Cancer–World Health Organization–North American Perfusion Group trial suggest that patients with melanomas of 1·5–3·0 mm in thickness who do not undergo elective lymph node dissection may have a locoregional control benefit from ILP. However, as long as a definite survival advantage for ILP has not been demonstrated, such treatment does not seem justified for these patients. The value of prophylactic ILP after resection of recurrent limb melanoma is also scientifically unproven. The potential prevention of further limb recurrence for only a limited period of time, as demonstrated in a rather small Swedish trial, probably does not justify routine use of ILP in these patients; a large international trial will be needed to assess whether ILP provides a survival advantage. For those with locally inoperable limb melanoma, ILP appears to be the treatment of choice since it results in complete disappearance of all macroscopic disease in a substantial proportion of patients, removing the need for amputation and providing palliation of symptoms. However, high limb recurrence rates and short duration of response need improvement. Results of alternative treatments should be compared prospectively with those of ILP in this clinical situation.

In 1957, Creech *et al.*[1] introduced the technique of isolated limb perfusion (ILP) in the treatment of melanoma. The main advantage of ILP is that by isolating a limb from the rest of the body a high dose of cytostatic drug (usually melphalan) can be given locoregionally, thereby minimizing systemic exposure to the drug and subsequent toxicity to vital organs. Isolation of the blood circuit of a limb is achieved by clamping the major artery and vein, ligating collateral vessels and applying a tourniquet around the base of the limb. After cannulation of the vessels, the isolated limb is provided with an artificial circulation by means of an oxygenated extracorporeal circuit, into which the cytostatic drug is injected. For melphalan, the concentration in the perfusion circuit is approximately ten times higher than that in blood at the maximum tolerated dose normally used for systemic administration[2,3]. After a period of isolated circulation, the limb is rinsed with an electrolyte solution, the cannulas are removed and the vessels repaired. Theoretically, the concept of ILP offers therapeutic advantages especially in the treatment of tumours with a relatively high tendency for locoregional recurrence, such as melanoma.

Unfortunately, the value of ILP remains controversial because of the shortcomings of most studies on its use[4–8]. Published results of ILP are typically limited to survival data, lack control groups, frequently contain small numbers of perfused patients, and often describe only a short follow-up. In many studies, the stage of disease and extent of associated surgery are not clearly defined.

In an effort to determine whether ILP has proven benefits, a literature search was performed using MEDLINE, the recent international surgical literature and the bibliography of articles collected. All reports that include a control group of non-perfused patients and/or provide objective response rates are reviewed here.

Prophylactic isolated limb perfusion as an adjuvant to local excision of primary melanoma

In a number of patients melanoma recurs locoregionally because of the microscopic involvement of local tissues, regional lymphatics and soft tissues between the primary and the first major regional nodal basin[5,9–13]. Risk factors for such recurrences are thick primary lesions, ulceration, location of the primary lesion on the sole of the foot or in the subungual tissue, regional node recurrence and inadequate surgical resection margins[5,12,13]. Treating an entire limb in an effort to eliminate these clinically undetectable tumour deposits makes sense, but can ILP really eliminate microscopic metastatic cells not removed by primary surgery and, the main objective, does this improve survival?

In the literature, six retrospective studies[14–21] using historical controls from the reporting institutions' own previous experience could be found. Results were not unanimously in favour of ILP: benefits could either not be demonstrated[14,18] or could be shown only in rather small subgroups of patients with more deeply invasive melanomas[17,19,20]. Some of these studies were performed when important prognostic factors, such as Breslow tumour thickness[22] and Clark level of invasion[23], were unknown. The perfused patients often formed a selected group[14–16,18,19,21,24], especially with regard to age, sex, tumour thickness, associated surgery and location of the primary lesion. In the light of the current knowledge of prognostic factors and more refined statistical techniques, these early studies with historical control groups appear to be of limited use in the assessment of the value of ILP.

Paper accepted 1 June 1996

Four studies[25–29] reported a more proper analysis of the value of ILP in primary melanoma by using matched controls for comparison. However, only one of these studies[28,29] was prospective in design. The pitfalls of using retrospective studies to assess the impact of ILP on outcome were amply illustrated by two reports from the Netherlands[25,26]. A group of patients from Groningen treated with wide excision and ILP with melphalan was retrospectively compared with a similar group of patients from Sydney treated with wide excision only[25]. The study was confined to women with a melanoma of the lower limb with Breslow thickness of 1·5 mm or more and Clark level IV or V; none underwent lymph node dissection. The two groups were similar in age, Breslow thickness, Clark level, ulceration and location of the primary lesion. Women with a melanoma of the leg (excluding the foot), who had been treated by excision and adjuvant ILP, had a significantly better 10-year disease-free survival rate (77 *versus* 45 per cent), a significantly higher 10-year overall survival rate (81 *versus* 60 per cent) and fewer locoregional recurrences (22 *versus* 54 per cent) than women treated by excision only. Curiously enough, for tumours of the foot, no significant benefits were observed from ILP. Subsequently, patients from Groningen were compared with another group of similar matched but non-perfused patients from a nearby region in the Netherlands and Germany[26]. The selection criteria to cross-match these two groups were: tumour location not in proximal third of upper arm or leg; Clark level III to IV; and Breslow thickness of 1·5 mm or more. In contrast to the previous comparison, no effect attributable to ILP was demonstrated in time to limb recurrence, time to regional lymph node metastasis, time to distant metastasis, disease-free interval or survival. This latter study by Franklin *et al.*[26] is theoretically superior to the former as variations in factors such as skin complexion and sun exposure were reduced to a minimum, patient groups were considerably larger and the authors performed a multivariate analysis to correct for all the relevant prognostic factors.

In the USA, 151 patients with primary melanoma treated with wide excision and ILP at the M.D. Anderson Cancer Center, Houston, Texas, were compared retrospectively with a similar matched group of 151 patients who underwent wide excision only at the University of Alabama and the University of Sydney[27]. Patients were individually matched for Breslow thickness, Clark level, site of the lesion and sex. Either of two drugs, melphalan and imidazole carboxamide, was used for ILP. No significant difference in either the disease-free or overall survival rate was found between the groups of patients using either drug. However, in a subgroup analysis of 25 patients with lesions thicker than 2·0 mm on the lower limb treated with wide local excision and ILP with melphalan, a significant improvement in both overall and disease-free survival was found.

In 1993, McKay *et al.*[28] had treated 64 consecutive patients with primary melanoma thicker than 1·5 mm by wide excision and ILP using melphalan since 1984. These patients were prospectively compared with 64 control patients, individually matched for sex, age, site of lesion and Breslow thickness but treated by wide excision alone. Overall survival analysis of both groups revealed no significant difference. However, analysis of patients with lesions of 1·5–3·0 mm in thickness suggested a benefit from ILP in terms of both time to first recurrence and survival. This study was updated in 1995[29], when it contained 120 consecutive patients and 120 individually matched controls. At that time, overall survival analysis of both groups revealed no significant difference. Neither was there a significant difference in survival with respect to sex, age, site or Breslow thickness. Because these matched comparative studies produced conflicting results, the need for prospective randomized trials was obvious[30,31].

In 1984, Ghussen *et al.*[32] reported the first randomized prospective study in which 37 patients with primary melanoma were randomized either to wide excision and regional lymph node dissection or to similar surgery plus ILP with melphalan. The local recurrence rate in the control group was 28 per cent and in the perfused group 5 per cent; this work was updated in 1989[33]. After a median observation time of approximately 6 years, the benefits of ILP (significantly better disease-free and overall survival rates) were again demonstrated[34]. This study has been criticized severely[5,10,30,35,36] for the small number of patients, the high recurrence rate in the control arm and the lack of a multivariate analysis.

A well designed multi-institutional study was conducted by the European Organization for Research and Treatment of Cancer (EORTC) Melanoma Cooperative Group, the World Health Organization (WHO) Melanoma Programme, and the North American Perfusion Group (NAPG) between 1984 and 1994[37,38]. In a prospective fashion, patients with a melanoma of at least 1·5 mm in thickness were randomized to wide excision with ILP or wide local excision alone. The decision to perform elective lymph node dissection was left to local policy. ILP was performed with melphalan, 10 mg per litre of tissue for the lower limbs and 13 mg/l for the upper limbs. Perfusion was done under mild hyperthermic conditions (38–40°C) for a duration of 1 h. After a median follow-up of 4 years, an interim analysis of 813 evaluable patients showed an overall improvement in disease-free interval after ILP ($P = 0·03$), with patients with tumour thickness between 1·5 and 3·0 mm without lymph node dissection benefiting most[39]. In patients without lymph node dissection, the occurrence of in-transit metastases as first sign of progression was reduced from 5·6 to 1·8 per cent and the occurrence of lymph node metastases from 22·6 to 16·6 per cent after ILP. No difference in overall survival could be detected. However, there was a trend towards improvement in survival with ILP for patients with melanomas 1·5–3·0 mm thick ($P = 0·07$); for those with thicker melanomas, there was no difference. For definite conclusions, the final results of this trial are eagerly awaited.

At this moment, ILP seems unjustified for patients with primary melanoma as a survival advantage has not so far been demonstrated. It does not make sense to use a laborious and expensive procedure that carries a definite risk of serious morbidity to prevent or delay locoregional recurrences in only a small percentage of patients. Such recurrences can generally be managed with local excision(s) or therapeutic lymph node dissection. Moreover, the recent emergence of selective lymphadenectomy based on lymphatic mapping presents a novel technique of detecting early lymphatic dissemination[40]. This approach reserves a major operation, i.e. regional node dissection, for only those patients with demonstrated lymphatic metastases. It involves a much less invasive, less morbid surgical procedure than ILP for prevention of clinically involved regional lymph nodes[40–43].

Prophylactic isolated limb perfusion as an adjuvant to excision of recurrent melanoma

The role of adjuvant ILP in recurrent melanoma of the limbs is more easily justified according to many authors[4–6,8,13,35,44–49]. In comparison to the reported 8–50 per cent 5-year survival rate following surgical excision alone for locoregional recurrence of limb melanoma[50], large series suggest that ILP improves survival (28–73 per cent) (*Table 1*)[50–57]. These observations, however, are subject to the criticisms inherent in retrospective analysis without controls; the apparently improved survival may be purely a result of patient selection[5,8,35]. Those receiving ILP possibly form a selected group in which the tumour biology is characterized by a low tendency for systemic manifestation combined with a rather high potential for locoregional recurrence[8,54]. Stringent screening for distant metastases and exclusion of such affected patients from ILP may also have been responsible for the survival benefit[8]. The belief that uncontrollable locoregional disease requiring amputation is seldom seen with ILP[30,35] cannot be substantiated.

A significant number of these patients will fail and again succumb to locoregionally recurrent disease, despite prophylactic ILP[5]. After ILP and resection of all macroscopic tumour tissue, limb recurrence rates are reported to be of the order of 36–50 per cent in large series[51,53,54,56]. The majority of these recurrences occur within 2–3 years of ILP[51,53,54,56], the median duration of the limb recurrence-free interval is between 5 (stage IIIAB) and 9 (stage II) months[54]. On the other hand, meticulous removal of in-transit metastases cures the disease often enough to make it difficult to compare the effectiveness of any adjuvant treatment[24].

In five retrospective comparative studies[14,15,46,58–60] of patients with recurrent melanoma, a significant advantage of ILP over excision alone could not be convincingly demonstrated. In only two of these studies[59,60] did ILP decrease the locoregional failure rate significantly; survival was not affected. Definite conclusions cannot be drawn because the treatment groups were too small, follow-up periods were too short, and the treatment groups were neither homogeneous nor matched for important prognostic factors, such as stage of disease, number of lesions, number of previous limb recurrences, tumour thickness and Clark level of the primary melanoma[54,57,61]. Therefore prospective randomized trials are needed to establish the value of adjuvant ILP in recurrent melanoma[59], just as in the case of primary disease.

In the previously mentioned severely criticized[5,10,30,35,36] studies of Ghussen *et al.*[32] locoregional recurrence rates in the control group were 32 (six of 19) and 59 (ten of 17) per cent for M.D. Anderson stages II and III respectively. In the ILP group analogous values were 6 (one of 18) and 13 (two of 16) per cent. The differences between the groups were significant and persisted after a median observation time of almost 6 years[33,34].

In 1991, the Swedish Melanoma Study Group[62] published the results of a prospective randomized trial involving 69 patients with recurrent melanoma (local recurrence, satellitosis or in-transit metastases). These patients were randomly allocated to radical surgery (36 patients) or radical surgery plus ILP with melphalan and limb temperatures of 40–41·5°C (33 patients). Stratification was employed for localization to an upper or lower limb. With a mean observation time of 39 months, the tumour-free survival time was enhanced in the ILP group from 10 to 17 months ($P = 0{\cdot}04$). The type of recurrence was similar in both groups, but further recurrences within the limb were fewer in the ILP group: six *versus* ten local recurrences, six *versus* nine in-transit metastases and three *versus* five regional lymph node metastases. Again, an overall survival advantage could not be demonstrated ($P = 0{\cdot}28$). The authors concluded that ILP cannot be recommended except in prospective randomized studies with a non-perfused control arm[62,63]. Because these future studies must achieve prolonged survival, large international trials will be needed[62].

Therapeutic isolated limb perfusion in locally advanced melanoma

With the advent of ILP, the need for amputation to control extensive limb melanoma has been reduced substantially[4,6,8,10,35,51,64–69]. Nowadays, such ablation is required only rarely for extensive or deeply infiltrative lesions associated with severe pain, bleeding and odour

not responding to ILP[68,69]. Although the main indication for ILP has traditionally been in-transit metastases not amenable to local surgery[6,8,24,31,35,70–72], data on objective response rates in large series are scarce[35,73,74]. All series in the literature that contained at least ten patients with measurable disease are summarized in *Tables 2–4*. Most data apply to recurrent disease; some include neglected primaries.

With ILP using melphalan, a mean complete remission rate of about 54 per cent can be obtained nowadays (*Table 2*). Complete remission rates have tended to improve over the years. ILP at the beginning of the perfusion era was associated with lower remission rates and complete remission rates have increased by approximately 10 per cent since 1988[35]. This may be attributed not only to the fact that most of the early ILPs were probably performed under less effective hypothermic conditions[35] but also because ILP schedules have become more sophisticated[35,74]. After ILP with melphalan, irrespective of tissue temperature, the median duration of complete remission ranges between 9 and 19 months, depending on the follow-up period[61,78]. In patients with complete remission, further limb recurrence develops in approximately 44 (range 24–54) per cent (*Table 2*) after a relatively short median interval of 5–10 months[57,61,72,85,102].

Strategies have been developed to improve the complete remission rate, such as multiple ILP schedules, application of hyperthermia, use of cytostatic agents other than melphalan and the introduction of biological response modifiers[74]. It is interesting to note that the complete response rates of 'controlled' normothermic ILP (tissue temperature between 37 and 38°C) and of ILP performed under 'mild' hyperthermic conditions (39–40°C) are within the same wide range (39–76 per cent)[61,71,72,84,86]. Only by using borderline 'true' hyperthermia (41–42°C)[57,80,81] or multiple ILP[103] do these complete response rates seem to improve significantly. No other drug is as effective as melphalan in the ILP setting, either as a single agent or in a multiple agent regimen (*Table 3*)[35,47,74].

A promising new development is the introduction of recombinant tumour necrosis factor (TNF) α to ILP (*Table 4*). The combination of this agent with interferon (IFN) γ and melphalan was first used by Lejeune's group in Brussels[96,104]. Complete remission was achieved in 17 of 19 patients with melanoma treated for stage IIIA or IIIAB disease, with the majority having five or more melanoma nodules after failure of previous ILP with either melphalan or cisplatin[96,104]. In a multicentre study[97], response rates from ILP with the combination of TNF-α, IFN-γ and melphalan remained high, with a complete remission rate of 91 per cent in 53 patients with stage

IIIA (34 patients), IIIAB (15) and IV (four) disease. After a median follow-up of 26 months, limb recurrence was observed in 21 (40 per cent) of these 53 patients, with a median duration of response of 14 months[86,97]. The mean number of lesions was 25, and 48 patients had more than five nodules. These response data were compared with those of 103 patients with similar stage III regionally recurrent melanoma, who were treated with standard melphalan ILP between 1980 and 1988 by the same teams[86]. Melphalan ILP alone produced a significantly lower complete response rate (52 per cent); in a multivariate analysis, the difference in complete response rates remained significant. However, although the median response duration has not yet been reached, the means were comparable: 3·9 years for patients receiving melphalan alone and 3·6 years for those receiving TNF-α, IFN-γ and melphalan[86]. Whether the addition of IFN-γ is necessary to achieve the 90 per cent complete remission rate is being addressed currently in a randomized phase II study[98]. Preliminary results show an 84 per cent complete remission rate in 31 patients after the triple regimen compared with 61 per cent in 33 patients when IFN-γ was omitted[98].

Data from similar recently reported trials from Italy have not confirmed these impressive findings (*Table 4*)[99,100,105–107]. Complete response rates with TNF-α, with or without IFN-γ, were 50–70 per cent[99,100,105–107] and most patients did not present with bulky disease as treated by Liénard *et al.*[97]. Regional relapse rates ranged from 15 to 50 per cent[100,105–107], with relapses occurring after only a short median period of 6 (range 3–14) months following ILP[100,105,107]. These figures and the Italian results after 'borderline' hyperthermic (41–42°C) ILP with melphalan alone were considered to be essentially the same[46,49,56,99,107], although the short follow-up of the TNF-α series does not allow any definite conclusions to be drawn[107]. Currently, the Surgery Branch of the National Cancer Institute, Bethesda, Maryland, is conducting a trial comparing the combination of TNF-α, IFN-γ and melphalan with melphalan alone in ILP[108].

Progress is allowing the ideal of a 100 per cent complete remission rate to be approached in several series[82,96,97,104]. However, most of these studies have a relatively short follow-up, without mention of the long-term durable complete response rate. In the few studies that do supply this information, the limb relapse rate after a complete remission is a disappointing 40 per cent and the corresponding limb disease-free interval is of only a short duration. It also remains difficult to assess what proportion of patients with irresectable melanoma can obtain good palliation with ILP, as most reports do not indicate whether responses were obtained in locally inoperable melanoma or, as probably was the case in many series, in recurrent disease deliberately left *in situ* to monitor the effect of ILP. Because the macroscopic tumour burden (as expressed by number of lesions, total tumour surface area and nodal status) is an important prognostic factor for tumour response and limb recurrence-free interval[57,61], these local control rates are probably too optimistic for patients with locally inoperable melanoma.

Toxicity and morbidity associated with isolated limb perfusion

Standardization of ILP technique and technological improvements have permitted a reduction of the most serious complications to a minimum[46,49]. Slight oedema, skin erythema and pain in a warm limb commonly occur approximately 48 h after ILP, and usually resolve within 14 days[49,109,110]. The redness fades to brown, which gradually becomes lighter over a period of 3–6 months; there is usually no visible abnormality after approximately 6 months. Other local manifestations, e.g. temporary loss of nails, drying or blistering of skin of palms of the hands or soles of the feet, and inhibition of hair growth on the limb, are sometimes seen[109,110]. From published data of large series one may conclude that more severe acute skin and soft tissue reactions (ranging from pronounced erythema and/or oedema associated with some blistering to, rarely, compartmental compression syndromes and reactions necessitating amputation) are seen in 7–37 per cent of perfused patients[111,112]. Factors that predispose to a more severe reaction are tissue temperature of 40°C or higher, female sex, deterioration of blood gas values of the perfusate, proximal isolation level, low flow rate, and pharmacokinetic parameters, such as high total melphalan dosage, high melphalan peak concentration, high concentration at equilibrium and a large area under the curve[111–114]. When these factors are taken into account,

Table 3 Complete response rates in patients with melanoma after isolated limb perfusion with drugs other than melphalan

Reference	Year	No. of patients	Complete response rate (%)	Drugs
Cox[58]	1975	28	36	Thiotepa, melphalan
Golomb[88]	1976	54	13	Thiotepa, actinomycin D, melphalan
Aigner *et al.*[89]	1983	12	17	Cisplatin
Aigner *et al.*[90]	1984	14	0	Vindesine, dacarbazine, cisplatin
Shiu *et al.*[91]	1986	19	32	Nitrogen mustard
Vaglini *et al.*[92]	1987	24	13	Dacarbazine
Coit *et al.*[93]	1988	12	0	Mouse monoclonal antibody R24
Coit[94]	1993	24	33	Cisplatin
Vaglini *et al.*[95]	1995	10	10	Interleukin 2 and LAK cells

Only series of ten or more patients are included. LAK, lymphokine-activated killer

Table 4 Complete response rates in patients with melanoma after isolated limb perfusion with melphalan, tumour necrosis factor α and interferon γ

Reference	Year	No. of patients	Complete response rate (%)	IFN-γ	Limb recurrence rate (%)*
Liénard *et al.*[96]	1992	29	90	Yes	
Liénard *et al.*[97]	1994	53	91	Yes	33
Liénard *et al.*[98]	1995	31	84	Yes	
		33	61	—

Di Filippo *et al.*[100]	1995	10	50	—†	
Fraker *et al.*[101]	1996				
TNF-α 4 mg		25	76	Yes	53
TNF-α 6 mg		11	36	Yes	25

Only series of ten or more patients are included. *In patients with complete remission; †temperature 41°C or more. TNF, tumour necrosis factor; IFN, interferon acute limb toxicity after ILP should be mild nowadays. This is extremely important as a strong correlation has been demonstrated between acute regional toxic reactions and the incidence of long-term morbidity, especially in the form of muscle atrophy/fibrosis and limb malfunction, which occurred in 11 and 15 per cent respectively of 367 patients at 1 year after ILP[115]. Only two other studies[116,117] focused on the issue of long-term morbidity, with conflicting results. In one report[117], no additional morbidity was noted after 'mild' hyperthermic (38–40°C) ILP compared with wide excision alone. In the other study[116], objective investigation after a median follow-up of 5 years after normothermic (37–38°C) ILP noted oedema or atrophy in three of 15 upper limbs and 15 of 42 lower limbs. The ankle proved to be particularly vulnerable with restriction of movement in more than 25 per cent of cases[116].

Mortality rates after ILP with melphalan range from 0 to 9 per cent[118], with deaths mainly reported in the beginning of the ILP era. Death usually resulted from pulmonary embolism, cardiac failure, renal failure or bone marrow depression. This last side-effect is reported to occur to some extent in up to 59 per cent of perfused patients[118] and is strongly associated with leakage of cytostatic drug into the systemic circulation[6,46,71,72,119], especially during the first 5–10 min of perfusion[72,119]. Systemic toxicity is negligible in the absence of significant leakage. Nausea and vomiting seem somewhat more pronounced after ILP than after other surgery of the same duration and extent[75,118,120]. It has been suggested that the combination of melphalan, anaesthetic agents, major surgery and postoperative narcotic analgesics may be a powerful emetogenic stimulus[120].

In contrast to the negligible incidence of severe systemic side-effects after modern ILP with melphalan, the complications associated with TNF-α in ILP can be impressive. Leakage of TNF-α, which unlike melphalan maintains a high stable drug level in the perfusate throughout ILP[104], can induce a systemic inflammatory response syndrome comprising fever and chills, hypotension and adult respiratory distress syndrome[97,104,105]. However, this toxicity can also be almost completely prevented by adequate control of leakage and extensive washout procedures at the end of perfusion[86,97,121,122].

Alternative methods of locoregional disease control

Since ILP was first described, attempts have been made to achieve similar results more simply using other regional chemotherapeutic techniques. Intra-arterial infusion of cytostatic agents and 'tourniquet infusion' with partial venous outflow occlusion are examples[123]. However, no other method has produced remission rates comparable to those of ILP. Recently, isolated limb infusion (ILI) has been developed as an alternative technique which is simpler than ILP[124]. Arterial and venous catheters are inserted percutaneously into the limb and a pneumatic tourniquet is inflated proximally. The cytostatic drug (melphalan), in 300–400 ml warmed saline, is infused rapidly through the arterial catheter. For 15 min it is continuously circulated via a simple warming coil by aspiration from the venous catheter and re-ejection into the arterial catheter, using a syringe and three-way tap. Of 12 patients treated by ILI, complete remission was obtained in six and partial remission in the rest. However, all complete responders experienced recurrence in the limb after a median interval of 11 months. Because of the simplicity and low morbidity, a routine double ILI protocol is currently being considered[124].

Local excision of individual lesions is impractical when they are numerous, large or recurring with a short disease-free interval[125–128]. Other methods of local ablation such as diathermy or cryosurgery may be used, but their efficacy has not been reported. Moreover, these techniques are not precise and a wide margin of normal tissue must be destroyed to ensure tumour necrosis. Carbon dioxide laser ablation of cutaneous metastases of melanoma has been described recently[125–129]. Because of its wavelength, carbon dioxide laser radiation is highly absorbed by soft tissues and so dissipation of heat to surrounding tissues by conduction is reduced, thus minimizing thermal damage. In a typical case ten to 15 lesions can be ablated under local anaesthesia in 15 min, but up to 450 lesions have been treated at one time. Recurrence at lasered sites is rare but, in any event, laser therapy can be repeated several times for subsequent recurrences with little morbidity. Its major benefit is that it can be carried out with little disruption to the patient's normal way of life. It is, however, important to appreciate that laser treatment is not suitable for all patients, particularly those with deep subcutaneous nodules or plaques, ulcerated or fungating lesions, and lesions larger than 1·5 mm in diameter.

Systemic chemotherapy, immunotherapy and local radiotherapy are of only limited effectiveness[130]. However, the addition of hyperthermia to radiotherapy in large doses per fraction has been reported as improving local tumour control with a complete response rate of 62 per cent (compared with 35 per cent using radiotherapy alone) with an acceptable level of complications[130]. The treatment consisted of three fractions at intervals of 4 days followed within 30 min by hyperthermia (43°C). Also, large nodules (greater than 4 cm) can be treated effectively; only 15 per cent of the 103 tumours that showed complete or partial responses regrew after a median response time of 10 months. This treatment combination is, however, suitable only for single or a few metastatic nodules. It is not yet widely available[131].

Conclusion

The major problem in assessing the true value of ILP in the management of melanoma is the lack of prospective randomized trials. In patients with 'high-risk' primary melanoma, preliminary results from the large international EORTC–WHO–NAPG trial showed a possible locoregional control benefit in those with lesions between 1·5 and 3·0 mm in thickness who did not undergo elective lymph node dissection. However, as long as a definite survival advantage has not been demonstrated, ILP does not seem indicated in patients with primary melanoma.

In the only available prospective randomized trial involving patients with recurrent limb melanoma, ILP delayed the occurrence of locoregional metastases, compared with excision of recurrences alone. Again, because no survival advantage was shown, a large international trial comparing ILP with simple excision or laser ablation is necessary to establish the value of ILP for this indication.

In patients with recurrent limb melanoma that is not suitable for local treatment, ILP is the treatment of choice. For this indication, ILP results in the complete disappearance of all macroscopic disease in a substantial proportion of patients, thereby palliating symptoms and removing the need for amputation. With modern perfusion techniques, limb and systemic toxicity is usually mild. However, the high limb recurrence rate and short duration of response need improvement. Results of alternative treatments should be compared prospectively with those of ILP in this clinical situation.

Review

Vascular complications of injecting drug misuse

K. R. WOODBURN and J. A. MURIE

Vascular Surgery Unit, The Royal Infirmary, Edinburgh, UK
Correspondence to: Mr K. R. Woodburn, Vascular Surgery Office, Department of Surgery, University of Edinburgh, The Royal Infirmary, Edinburgh EH3 9YW, UK

Drug misuse is now a significant problem in western society; many different pharmaceuticals are administered by drug abusers as intravenous preparations. This has resulted in an increasing number of complications associated with prolonged intravascular and perivascular injection of abused substances. These complications of intravenous drug abuse may lead to limb-threatening arterial injuries that present a considerable management problem in patients who often have significant co-morbidity. This article provides a comprehensive review of the vascular complications that result from drug misuse by injection. It discusses the aetiology and clinical features of these complications and highlights the limited role of both the general surgeon and specialist vascular surgeon in the management of these patients.

The number of injecting drug abusers in the UK is unknown, but a random survey carried out in Scotland of 5000 adults between the ages of 15 and 59 years indicated that just under 1 per cent of this age group have injected drugs at some time[1]. In the Edinburgh urban area the prevalence of currently injecting drug abusers in the same age group is estimated at four per 1000 (95 per cent confidence interval (c.i.) 3·0–5·5 per 1000), the rate doubling if addicts who have injected at any time in their drug abusing career are included (Davies AG, personal communication). The relatively large number of injecting drug abusers has led to increased recognition of arterial and venous complications associated with the parenteral administration of abused drugs and, although most general surgeons encounter these problems infrequently, they present considerable difficulty in diagnosis and management, particularly in regions where there is a high prevalence of human immunodeficiency virus (HIV) infection in the drug abusing population. The prevalence of HIV infection in injecting drug addicts in Scotland ranges from 0·8 per cent in Glasgow[2] to 19·7 (95 per cent c.i. 15·5–23·9) per cent in the Edinburgh area[3].

The vascular complications of drug abuse tend to occur after prolonged drug administration leading to an absence of easy peripheral venous access because of the phlebitis associated with repeated non-sterile injection. The addict eventually attempts to administer drugs into a major deep vein, commonly in the groin, with a substantial probability of vascular injury occurring. This may take the form of direct intra-arterial injection which can lead to limb ischaemia, either primarily as a consequence of direct local arterial injury and occlusion or as a result of distal small vessel damage, depending on the nature of the preparation used. Infective vascular complications may also result, such as pseudoaneurysm, which may arise after repeated perivascular and intravascular injection of non-sterile preparations.

Intra-arterial injection

Accidental intra-arterial injection resulting in limb ischaemia and tissue necrosis was first reported in relation to the medical administration of parenteral preparations of the barbiturate thiopentone[4,5]; similar sequelae have been reported following intra-arterial injection of oral barbiturate preparations in intravenous drug addicts[6,7]. Limb ischaemia and tissue necrosis in drug abusers have subsequently been reported after intra-arterial injection of oral preparations of a wide variety of drugs[8,9], including a recent series of cases associated with the use of 'abuse-resistant' temazepam gel capsules[10–12].

Clinical features

Despite the wide variety of pharmaceuticals involved, including parenteral formulations administered under medical supervision as well as addict-prepared solutions of crushed tablets or powder, liquid contents of capsules and solid gel preparations, the clinical features reported in most cases of intra-arterial injection are remarkably similar. Initially the patient has an intense 'burning' pain in the distribution of the artery injected; this occurs immediately following intra-arterial injection[5–8,10–16]. Although the pain may be accompanied by a hyperaemic flush in the same region[14], drug abusing patients rarely present to hospital at this early stage. The initial symptoms are followed within a few hours by a constant pain and patchy mottling of the affected limb, consisting of areas of pallor and purplish erythema with cyanosis of the digits, together with marked swelling of the limb (*Fig. 1*). The patchy mottling may be observed in tissue proximal to the site of intra-arterial injection. Pain is exacerbated by any movement of the affected limb and, although at this early stage there is no demonstrable neurological deficit, limb swelling can lead to the development of a compartment syndrome and rhabdomyolysis[5–8,10–13] (*Fig. 2*). Most patients have pulses in the affected limb, despite the clinical picture of patchy ischaemia; the subsequent development of tissue necrosis and gangrene is a variable event[5–12] (*Fig. 3*).

Aetiology and pathology

Inadvertent intra-arterial injection of thiopentone during the induction of anaesthesia was thought initially to produce symptoms as a result of thrombosis within the injected vessel, secondary to intimal damage caused by the

Paper accepted 13 June 1996

high pH of thiopentone in solution. This was considered to be accompanied by marked distal arteriolar and venous spasm, and diffuse venous thrombosis leading to muscle ischaemia and limb swelling, with eventual tissue necrosis and limb loss[5]. Some animal studies using a rabbit ear preparation support this pattern of marked acute venospasm with venous thrombosis, together with patchy arterial spasm and intra-arterial thrombosis, following injection of thiopentone[17,18]. However, the arterial effects observed in these studies may actually have been related to the design of the experimental model, and other animal studies have indicated that intra-arterial injection of a number of commonly abused drugs fails to produce any significant arterial spasm, and has a vasodilatory effect in most instances[19,20].

It is of interest to note that major tissue loss following intra-arterial injection of barbiturates occurs only in patients in whom one or more major vessel is occluded, as determined either angiographically or by clinical examination[5–7]. In these patients thrombosis and occlusion take place at the site of injection, often several days later, presumably reflecting direct local intimal damage at the time of injection, as postulated by Cohen[5] and supported by the animal studies of Williams and Montgomery[21]. Undoubtedly the limb swelling observed in such patients occurs as a consequence of ischaemic muscle necrosis (*Fig. 4*), while the limb mottling reflects local venous stasis following acute arterial occlusion.

In most patients, however, intra-arterial injection of barbiturates and other drugs is accompanied by a full complement of distal pulses and all the clinical features of

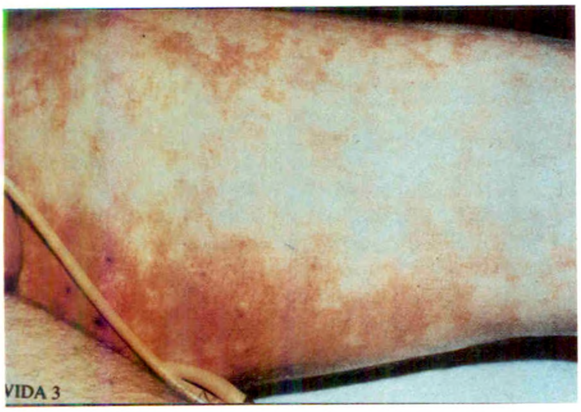

Fig. 1 Characteristic early mottling of the thigh following inadvertent injection of temazepam gel into the femoral artery

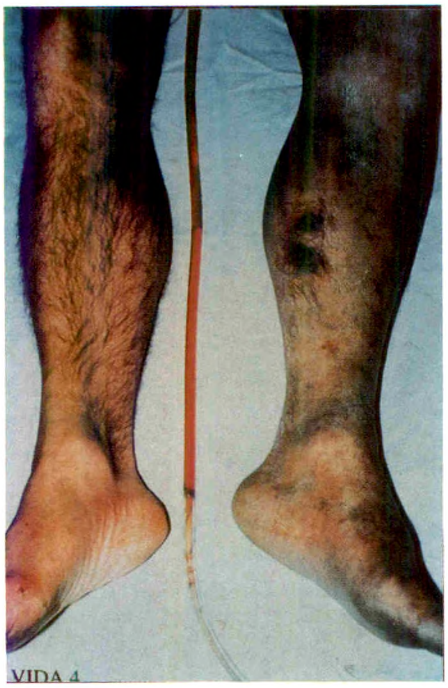

Fig. 2 A painful, tense, mottled limb following intra-arterial injection of temazepam gel. The tube draining the urinary catheter shows myoglobinuria due to rhabdomyolysis. This patient underwent thigh and calf fasciotomy shortly after this picture was taken

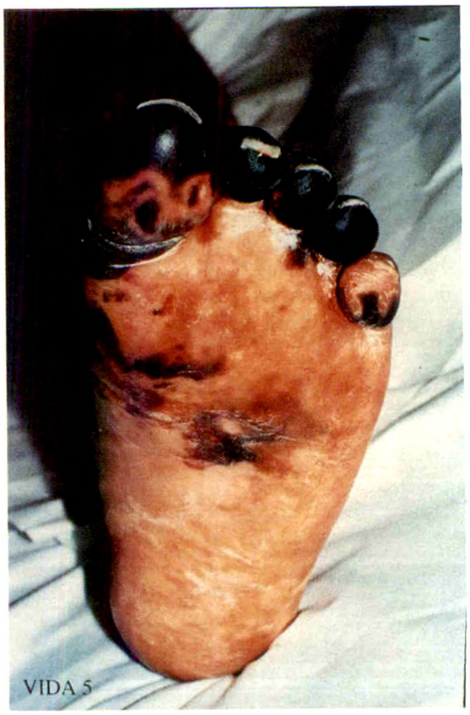

Fig. 3 Development of digital gangrene several days after intra-arterial injection into the right femoral artery

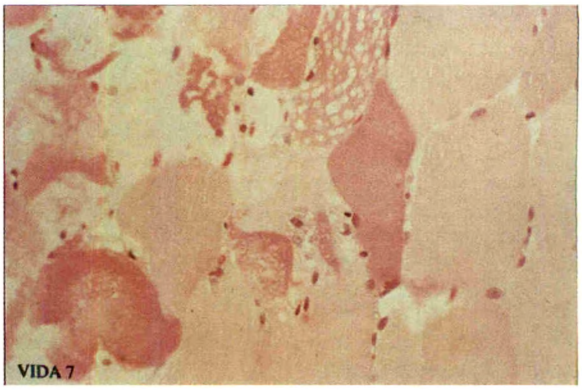

Fig. 4 Histological appearance of a muscle biopsy obtained at the time of fasciotomy following intra-arterial injection of temazepam gel. The patchy vacuolation of myocytes can be seen, with viable myocytes alongside. (Haematoxylin and eosin stain, original magnification × 120)

intra-arterial injection already described[5–13]. Despite the absence of major vessel occlusion there is no doubt that some of the inert components, such as corn starch and talc, which are commonly present in the drug addicts' preparation, can produce transient vasospasm and particulate microemboli leading to microvascular occlusion[7,8,19,20]. This is supported by the observation that particulate microemboli are found in the pulmonary circulation after intravenous injection of abused drugs[22,23]. Spasm in smaller digital vessels has been shown angiographically following intra-arterial injection of temazepam gel[12]. While these features undoubtedly contribute to the clinical presentation, there is evidence that the damaging effects of intra-arterial injection may also be related to venospasm and venous thrombosis[5,13,17], together with a diffuse chemical arteritis as a consequence of endothelial injury[18,21,24].

The overall effects of intra-arterial injection probably arise as a combination of particulate emboli, vasospasm in distal vessels, and endothelial injury leading to small vessel vasculitis and venous thrombosis. These changes produce a picture of diffuse tissue ischaemia, which may be exacerbated if the patchy muscle necrosis that results[11,24] leads to the development of a compartment syndrome with major muscle necrosis. It is this predominantly small vessel and venous damage that gives rise to the clinical picture of limb mottling and swelling with muscle tenderness, in the presence of a full complement of pulses. On the other hand, in the few patients who present with an absent major limb pulse at the site of injection, the postulated mechanism is one of thrombosis following direct mechanical and chemical injury of the vessel at the time of injection[5,21].

Treatment and outcome

In spite of the relatively constant clinical features following intra-arterial injection, the heterogeneity of compounds injected, the small numbers seen by individual clinicians, and the difficulties inherent in treating and following up this difficult group of patients have resulted in a wide variety of putative treatment regimens. Nevertheless, both the requirement for surgical intervention and the eventual outcome are remarkably similar in most series (*Table 1*). There is general agreement, unless major proximal limb pulses are absent, that investigation with a view to reconstructive vascular surgery is not indicated[9,12]. Some authors have attempted a stellate ganglion block following intra-arterial injection in the upper limb but this has not been found to be of benefit[13,15]. The role of fasciotomy is unclear but, in view of the common features of widespread patchy muscle necrosis and tissue oedema[11,24], it may be of some value in the lower limb to prevent renal failure from rhabdomyolysis[10,11], and in the upper limb to prevent subsequent ischaemic contracture[15,25]; however, rhabdomyolysis is likely to result from microvascular thrombosis and subsequent ischaemic muscle necrosis rather than be secondary to a rise in compartment pressures. As *Table 1* indicates, few series of intra-arterial injection reported a high incidence of renal failure, suggesting that fasciotomy should be withheld unless compartment pressure monitoring demonstrates a rise in compartment pressure accompanied by the clinical features of a compartment syndrome. This policy was employed successfully in three cases of upper limb intra-arterial injection reported by Silverman and Turner[26].

Most authors stress the use of intravenous heparin to prevent propagation of intravascular thrombus and to maintain patency of collaterals[5,9,12–15]. This is probably appropriate in view of the extensive arterial and venous thrombosis observed in both animal and pathological studies[13,17,18,24]. Heparin therapy should be continued until limb swelling, pain and mottling have subsided[14], usually between 5 and 10 days after injection[12–14], although in this group of patients early self-discharge often supervenes before this. There is little evidence to support the use of either intra-arterial vasodilators[14,15] or prostacyclin infusion[12], presumably because of the transient nature of the vasospasm that follows intra-arterial injection[17,19,20], although encouraging results following treatment with the prostacyclin analogue, Iloprost, have been reported in one small series[27]. Intra-arterial thrombolysis has rarely been applied in this situation and is, in any event, likely to be difficult to sustain in a group of patients who commonly discharge themselves early from hospital against medical advice[9,14]. Silverman and Turner[26], however, have reported encouraging results after treating a small number of complications of intra-arterial injection using this method.

Supportive medical therapy is, therefore, the best treatment in patients with a full complement of limb pulses following intra-arterial injection. Analgesia should be administered if required, careful monitoring of renal function should be carried out and the patient should be systemically heparinized. Although venous access may require insertion of a central venous catheter in these patients, invasive surgical procedures are rarely indicated, with the exception of fasciotomy in selected cases. Rarely a patient will present with absent proximal limb pulses in the presence of a salvageable limb and in this situation investigation is needed with a view to vascular reconstruction.

Table 1 Outcome following inadvertent intra-arterial injection of abused drugs

Infective vascular complications

A wide variety of infective complications arising as a consequence of poor aseptic technique and parenteral injection of non-sterile preparations in injecting drug abusers has been documented[15,22,28]. It is a commonly held belief that superficial thrombophlebitis and deep vein thrombosis are prevalent in injecting drug addicts[22], although these complications rarely present to surgeons, and their occurrence is poorly documented in the literature. Nevertheless one recent report suggested that as many as 40 per cent of admissions following intravenous temazepam misuse were for deep vein thrombosis[29]. There are, however, some local vascular complications related to infection that are more likely to present to the general or vascular surgeon.

Infected venous pseudoaneurysm

Venous pseudoaneurysm is an infrequently reported complication of injecting drug misuse. In a retrospective review of 172 cases of arterial injury associated with drug injection, Benitez and Newell[16] reported ten venous pseudoaneurysms and 134 arterial pseudoaneurysms; two venous pseudoaneurysms were reported in 32 vascular complications of drug injection reported by Yeager *et al.*[30] There are no reports of venous pseudoaneurysm at sites other than the common femoral vein. In 1984, Johnson *et al.*[31] commented that pseudoaneurysms develop after septic phlebitis of the vein induced by repeated injection under non-sterile conditions. It was suggested that some cases arise when the infected vein ruptures and the communication into the infected haematoma fails to close. Alternatively, in some instances the pus-filled vein may communicate with surrounding tissue via the venepuncture site. Regardless of the exact aetiology of the condition, the diagnosis of venous pseudoaneurysm is usually made at operation in a patient who presents with groin pain, fever, leucocytosis and, sometimes, a fluctuant groin mass[16,31]. Preoperative investigation rarely enables the diagnosis to be made before surgery[16], which consists of excision of the infected pseudoaneurysm with excision and ligation of the infected common femoral vein[16,31]. In view of the high incidence of bacteraemia in these patients, systemic antibiotic therapy should be commenced on admission. The organisms isolated in such patients include *Staphylococcus aureus*, *Escherichia coli*, and *Streptococcus* spp.[16,31] but, in view of the manner of preparation of injections by addicts and the high incidence of HIV infection in some addict populations[3], it seems prudent to ensure broad-spectrum cover until bacteriology results become available.

Arterial pseudoaneurysm

First reported in injecting drug misusers in the 1960s[32], infected pseudoaneurysm or 'aneurysmal abscess' has become one of the commonest vascular complications found in drug addicts[14–16,30]. Although infected pseudoaneurysm in this patient population is reported to occur in brachial and radial arteries[16,33,34], the majority of infected pseudoaneurysms associated with injecting drug misuse develop in the femoral artery[16,30,33–38].

Pseudoaneurysm commonly presents as a painful swelling, with fever and leucocytosis also prevalent[16,34], although it may present with intermittent bleeding[35] and, occasionally, massive haemorrhage[31,36,37]. The typical features of an indurated, erythematous swelling may be mistaken for a simple abscess on initial presentation[33], but the majority of pseudoaneurysms are pulsatile on examination, with an audible bruit over the swelling[16]. Nevertheless, since up to 23 per cent of pseudoaneurysms are non-pulsatile[16], careful clinical examination and a high index of suspicion are required in the assessment of any infected groin swelling in an injecting drug addict. Misguided attempts at incision and drainage of a presumed 'abscess' must be avoided.

Drug addicts presenting with infected swellings in the vicinity of a major vessel should undergo duplex ultrasonography to determine whether or not the lesion contains flowing blood, confirming the diagnosis of pseudoaneurysm. Although the use of ultrasonography is not universally advocated[37] and it may lead to a false-negative diagnosis[16], there is little need to carry out routine arteriography unless diagnostic doubt exists[35]. The high incidence of positive bacteriological cultures from both systemic blood and the aneurysm itself, with *Staphylococcus* and *Pseudomonas* occurring commonly[16,33,38], and a significant likelihood of mixed infection[37], make broad-spectrum antibiotic therapy mandatory. The infective risks to operating theatre personnel posed by injecting drug users[3,39] may be reduced by adequate operative exposure of involved vessels; early proximal and distal control of arteries and veins is the safest technique[33,39].

There is no doubt that infected pseudoaneurysm is one of the few indications for vascular surgical intervention in injecting drug addicts. The most appropriate form of intervention for femoral false aneurysm has, however, been the subject of some debate, especially regarding whether or not revascularization should be carried out in all cases at the time of wide surgical debridement of the cavity and ligation of the involved vessels[37,38,40]. Infected pseudoaneurysms of the upper limb vessels seem to require neither revascularization nor amputation after excision and ligation[16,33] (*Table 2*).

Revascularization following ligation and resection of an infected femoral aneurysm often requires the use of a synthetic graft because of the lack of good quality vein in drug abusers[38]. This has been associated with a significant incidence of graft infection and occlusion[36,39], although in many cases occlusion of the graft does not lead to limb loss[39]. A policy of excision and ligation of the aneurysm, with subsequent revascularization where there is postoperative evidence of limb threat, has been advocated by some authors[33,37] as a means of reducing the number of revascularization procedures. This is particularly suitable for patients who undergo common femoral artery ligation alone, which is associated with a low risk of subsequent amputation[37], and the overall limb salvage rates reported after compulsory revascularization are no better than those reported following a policy of selective revascularization (*Table 2*). Most authors report a higher risk of limb threat following ligation of all three groin vessels (common, superficial and deep femoral)[33,35,37]; however, even in this group of patients only a small minority require revascularization[35,37], although most will develop claudication[35]. The overall risk of limb loss after surgery for infected femoral pseudoaneurysm is approximately 10–20 per cent[16,37], although in cases requiring triple femoral vessel ligation this may be as high as 33 per cent[37].

Where revascularization is required it has been suggested that remote iliofemoral bypass using either the

obturator route[37,38], or the lateral thigh route[36,39] is to be favoured over direct interposition grafting in the groin. Placing a synthetic iliofemoral interposition graft in the groin after excision and ligation of an infected femoral pseudoaneurysm results in graft occlusion, infection and haemorrhage which may be less frequent following remote synthetic grafting (*Table 3*). The results of direct interposition grafting with autogenous vein, if available, may reduce these complications[37] although anastomotic disruption is a likely complication in the early postoperative period following all types of interposition grafting[39]. The most prudent course in the treatment of infected femoral pseudoaneurysm would therefore appear to be one of excision and ligation with selective revascularization using an iliofemoral graft (vein or synthetic) placed at a site remote from the involved groin.

Conclusion

Despite the increase in drug misuse by injection and the wide variety of complications encountered in drug abusers, only a limited number of retrospective reports have addressed the problem of vascular complications. It does, however, appear that the need for specialist vascular surgical referral is more or less limited to infected femoral pseudoaneurysm. This lesion should be suspected in any injecting drug addict with an appropriately sited swelling; it must be identified before surgery if safe and appropriate treatment is to be achieved. The risk of limb loss after operation should be clearly explained to these patients. With the exception of infected venous pseudoaneurysm, which is usually diagnosed at operation to drain an abscess, surgery has little part to play in the management of other vascular complications of drug injection; supportive medical therapy is often all that is required.

Review

Aetiology and treatment of anal fissure

J. N. LUND and J. H. SCHOLEFIELD

Department of Surgery, University Hospital, Nottingham NG7 2UH, UK
Correspondence to: Mr J. H. Scholefield

Anal fissure is a common problem that causes significant morbidity in a young and otherwise healthy population. Treatment has remained largely unchanged for over 150 years and the pathogenesis of this condition is not yet fully explained. Acute fissures should be treated conservatively with dietary modification. Chronic fissures do not respond to conservative treatment. The current recommended surgical treatment for chronic fissure is lateral internal sphincterotomy. However, there is a disturbance of continence in a sizeable proportion of those undergoing this procedure. As yet there is no proven non-surgical treatment for chronic fissure. Although local injection of botulinum toxin and the topical application of nitrates show early promise, further controlled trials are needed.

A systematic review of the aetiology and treatment of anal fissure has been performed. European language literature between the years 1975 and 1995 was assayed from Medline. Historical articles were identified from citations in these articles.

Anal fissure is a split in the skin of the distal anal canal. It is a common complaint in young adults with a roughly equal incidence in both sexes[1]. Acute fissures are probably very common and most heal spontaneously, but a proportion progress to form a chronic linear ulcer in the anal canal and show great reluctance to heal without intervention. Classic symptoms are pain on or after defaecation which is often severe and which may last from minutes to several hours. Often there is bright blood on the toilet paper. Patients may also complain of pruritus.

The majority of anal fissures occur in the posterior midline of the anal canal but 10 per cent of fissures in women and 1 per cent in men occur in the anterior midline[2]. Multiple fissures or fissures occurring in the lateral position arouse suspicion of other diseases including Crohn's disease, ulcerative colitis, tuberculosis, human immunodeficiency virus or syphilis. However, the majority of fissures seen in patients with inflammatory bowel disease occur in the posterior midline and are painful in at least half of cases[3,4].

The fissure may be seen as the buttocks are parted. Anal fissure is often suspected because there is marked spasm of the anus making examination difficult. Digital or proctoscopic examination is often impossible because of pain experienced by the patient. Under a general anaesthetic the fissure is seen as a linear or pear-shaped breach in the lining of the anal canal below the dentate line. Acute fissures are generally differentiated from chronic fissures by their appearance. Acute fissures are superficial splits in the anoderm with sharply demarcated edges. When the fissure is chronic, induration at the edges of the fissure may be seen and the horizontal fibres of the internal anal sphincter (IAS) may be visible in the base. There is a notable lack of granulation tissue at the base of the fissure. A skin tag may be present distally. Although there is no strict temporal definition of chronicity it is suggested that any patient with persistent symptoms for more than a few weeks will usually have a chronic fissure[2,5].

Physiological and pharmacological control of the internal anal sphincter

The human IAS exists in a state of partial contraction and relaxes in response to rectal distension (the rectosphincteric reflex). Sympathetic innervation from the fifth lumbar segment via the hypogastric nerves is responsible for a proportion of the tonic contraction but there is also a large myogenic component[6,7]. Contraction of isolated strips of human IAS is mediated by α-adrenoceptors. Relaxation is mediated by β-adrenoceptors[8]. The α-adrenoceptor population is dominant as the contractile response to noradrenaline can be converted to relaxation only when selectively blocking α-adrenoceptors[8]. These results are supported by experiments on normal volunteers[6]. Acetylcholine has a predominantly inhibitory effect on isolated IAS tone mediated by muscarinic receptors[8,9].

Electrical field stimulation (EFS) mimics the effect of extrinsic nerve stimulation of isolated smooth muscle strips. Human IAS relaxes in response to EFS. This relaxation is abolished by tetrodotoxin, a universal neurotoxin, indicating that the relaxation is nerve mediated[8]. Relaxation induced by EFS is unaffected by antagonists of acetylcholine and is therefore mediated by a non-adrenergic, non-cholinergic (NANC) neurotransmitter. Adenosine triphosphate and vasoactive intestinal polypeptide have both been suggested as candidates for NANC neurotransmission but their role has not been substantiated in man[8,10]. It seems likely that NANC neurotransmission is mediated by nitric oxide.

In an animal model Rattan and Chakder[11] demonstrated concentration-dependent relaxation of the IAS in response to nitric oxide which was similar to that seen in NANC nerve stimulation by EFS. NANC nerve-mediated IAS relaxation was blocked by inhibition of nitric oxide synthase (NOS) with L-NNA(N^5-(nitroamidino)-L-2,5-diaminopentanoic acid. This blockade was reversed stereoselectively by L-arginine, a substrate for NOS. Nω-nitro-L-arginine, an inhibitor of the L-arginine–nitric oxide pathway, produced a concentration-dependent reduction in opossum IAS relaxation to EFS[12]. Nitric oxide was released following EFS of NANC neurones from isolated muscle strips of opossum IAS using a chemiluminescence method for detecting nitric oxide[13].

Paper accepted 7 June 1996

O'Kelly *et al.*[14] demonstrated the presence of neurones containing NOS in the rectal myenteric plexus which ramified throughout the IAS and lay in close proximity to smooth muscle cells. In Hirschsprung's disease, a condition in which the rectoanal inhibitory reflex is absent, nerves containing NOS were absent from the non-relaxing segment but present in the normal segment of gut[15]. Although nitric oxide release was not demonstrated directly, its involvement in nerve-mediated relaxation was strongly suggested by *in vitro* studies on human IAS[16].

Pathogenesis of anal fissure

Historical perspective

The passage of a hard stool bolus has traditionally been thought to cause anal fissure. Ball[17] suggested that the passage of a hard stool tore down an anal valve leaving the coiled up skin at the anal verge as the sentinel pile. This does not explain why fissures tend to occur in the midline and anal valves can still be seen at the upper end of a fissure. Fibres of the superficial external anal sphincter decussate to form a Y shape posteriorly; the overlying skin was said to be poorly supported and was prone to tear on passage of a large stool[18]. However, a history of constipation preceding the onset of anal fissure is obtained only in one of four cases and diarrhoea is seen to be a predisposing factor in 4–7 per cent of patients[5 19 20].

Varicose veins of the anal canal have been implicated in the formation and persistence of anal fissure; Miles[21] suggested that these varicosities were the result of a 'pecten band' in the distal anal canal and that the fissure persisted because of phlebitis of these vessels. Division of this 'pecten band' was advised as treatment. It was later shown by Eisenhammer[22] that this band was in fact the hypertonic IAS.

Anal fissure may be associated with childbirth in between 3 and 11 per cent of patients and commonly occurs in the anterior midline[5 23 24]. Shearing forces from the foetal head on the anal mucosa or mucosal tethering after childbirth rendering it more susceptible to trauma have both been incriminated but are difficult to substantiate.

Spasm of the anal sphincter has been noted for many years in association with anal fissure and surgical treatment has generally been aimed at overcoming this spasm[25]. Brown and colleagues[26] found that the IAS of patients with anal fissure was fibrotic compared with that of controls. It was postulated that a myositis occurs early in the course of a fissure and that this is the underlying cause of both spasm and fibrosis. However, the cause of the spasm remains obscure.

Early reports[27–29] failed to demonstrate raised anal pressure in small groups of patients with anal fissure. However, the majority of studies have consistently found resting anal pressure to be significantly higher in patients with anal fissure than in normal controls using a variety of techniques[30–43]. Maximum voluntary squeeze pressure in patients with fissure is no different from that in controls, suggesting that the high resting pressure is due to hypertonicity of the IAS. Application of local anaesthetic to the fissure has no effect on resting anal pressure[41]. Also, resting anal pressure in patients healed by conservative treatment tends to increase to pretreatment level while the patient remains symptom free[44]. Both of these observations suggest that the spasm of the IAS is not secondary to local pain. An abnormal anorectal inhibitory reflex and a longer high-pressure zone has been noted in patients with chronic anal fissure but is not a consistent finding[28,30,32,39,45,46]. Ultraslow pressure wave activity occurs more frequently in those with chronic anal fissure than in controls[33,39]. This activity is abolished after sphincterotomy.

Current theories

The blood supply of the distal anal canal is via the inferior rectal arteries, branches of the internal pudendal artery. These vessels cross the ischiorectal fossae and divisions pass through the anal sphincters to reach the mucosa. Post-mortem angiography of the inferior rectal artery was performed in 41 subjects by Klosterhalfen *et al.*[47]. Two variants of the inferior rectal artery were demonstrated. In the first, a paucity of branches of the inferior rectal artery was seen at the posterior commissure. This variant was noted in 85 per cent of cases. In the second, the inferior rectal artery supplied branches to the posterior commissure as well as to other parts of the distal anal canal. Morphometric study of the capillaries revealed them to be less dense in both the subanodermal space and within the IAS in the posterior midline in the majority of subjects. It was suggested that ischaemia of the posterior midline may explain the predilection of anal fissures for this position and the lack of granulation tissue seen in the base of a chronic anal fissure.

Raised pressure of the IAS associated with anal fissure reduces the perfusion pressure of the mucocutaneous lining to levels equivalent to a perfusion index of 0·29, which may produce rest pain and ulceration when seen in the lower limb[36]. Internal anal sphincterotomy or anal dilatation, which lower the pressure exerted by the IAS, may restore normal perfusion of the anoderm leading to relief of pain and healing of the fissure. Schouten and colleagues[48] demonstrated reduced blood flow at the posterior commissure of the anal canal compared with that in the other three quadrants using laser Doppler flowmetry. Anodermal blood flow was negatively correlated with resting anal pressure. When resting anal pressure fell under anaesthesia, a rise in anodermal blood flow was noted. After lateral sphincterotomy a significant fall in resting anal pressure and a significant rise in anodermal blood flow was observed to levels seen in controls[49]. It seems that ischaemia may play an important part in the pathogenesis of chronic anal fissure.

Treatment of anal fissure

Non-surgical

Since the passage of a hard stool has been thought to contribute to the development of anal fissure the avoidance of constipation has been used as treatment for many years[50 51]. In a prospective case–control study, a diet that contained raw fruit, vegetables and wholegrain bread significantly decreased the risk of developing anal fissure. Significantly increased risk of developing a fissure was noted in those who frequently consumed white bread, sauces thickened with roux, and bacon or sausages[52]. In treatment of acute anal fissure, dietary bran supplements and warm sitz baths were shown to be superior to topically applied local anaesthetic or hydrocortisone cream, healing 87 per cent after 3 weeks[53]. Recurrence of acute fissure was also significantly decreased when 5 g unprocessed bran was taken three times daily compared with that after placebo (lactulose) and 2·5 g bran[54]. There are no trials examining the effect of diet on the course of chronic anal fissure. Following local anaesthetic treatment[55] of pruritus ani, Gabriel[56] and Morgan[57] treated a mixture of acute and chronic fissures by injection of local anaesthetic solutions into the sphincter on either side of the fissure[55–57]. Healing was seen in less than half of the patients and many complained of severe pain following injection lasting for several hours. Injection was often complicated by local sepsis and temporary incontinence, and was largely abandoned[2,58]. Local injection of sclerosant was also complicated by sepsis and many patients suffered early relapse[59].

Avoiding operation by means of applying a pharmacological preparation locally has been attempted since the early 19th century when belladonna suppositories were used but were later abandoned because of systemic side-effects[25,60]. There are presently over a dozen proprietary preparations available in the UK which may be applied topically to alleviate the symptoms of anal fissure. Preparations contain soothing agents, such as bismuth subgallate or zinc oxide, often in combination with local anaesthetics or topical steroids. The majority of these preparations have not been evaluated in scientific trials.

Dietary supplements of unprocessed bran, topical lignocaine 2 per cent gel or topical hydrocortisone 2 per cent ointment were compared in a prospective randomized trial in patients with acute fissure[53]. No difference was seen in symptomatic relief between groups but significantly fewer fissures healed in patients treated with local anaesthetic (60 per cent) than in the other two groups (82–87 per cent). One patient treated with hydrocortisone developed extensive previously undiagnosed anal herpes. The use of local anaesthetic agents may occasionally lead to sensitization of the skin[61]. Two other studies[19,20] using lignocaine gel in the treatment of acute fissure found that half of the patients were referred for surgery and that, of those initially cured, half would eventually relapse. It was suggested that the presence of a skin tag or fibrous anal polyp were significant predictors of failure to respond to conservative treatment and that local anaesthetic treatment be reserved for acute fissure. However, healing was observed in 45 per cent of patients with symptoms of over 6 months' duration when treated with lignocaine gel; over half of these patients had sentinel tags[24].

Anal dilators have been employed in the treatment of anal fissure for many years[25,62]. They were popular for some time but have been criticized as being merely a reliable way of applying an anaesthetic ointment[2,20]. It was recommended that the instrument, usually a St Mark's dilator of medium size, be coated in anaesthetic jelly and inserted into the anal canal before the passage of stool to prevent exacerbation of symptoms during defaecation, and at two or three other times during the day[20]. Two small studies[58,63] reported that more than half of the patients were initially cured using this technique but that half of those cured would relapse; a larger retrospective study at St Mark's Hospital, London, confirmed these results[20]. The majority of those who were cured initially had acute fissure. Conservative treatment was found to be inferior to lateral internal sphincterotomy in 308 patients with acute and chronic fissures[44]. Later prospective randomized trials, comparing the use of an anal dilator plus anaesthetic jelly with digitally applied anaesthetic jelly alone reported no difference between the two groups for acute fissure[19] or chronic posterior fissure[24]. Overall, almost half of the patients in each group were referred for surgery, although a retrospective analysis of patients with anterior fissure suggested that this fissure may respond better to conservative therapy[24].

A combination proprietary ointment Proctosedyl (Roussel Laboratories, Uxbridge, UK), containing cinchocaine hydrochloride and hydrocortisone, was used in the treatment of acute fissure with an overall healing rate of 80 per cent[64]. This trial was uncontrolled and involved 133 patients including infants, children and adults seen in 45 general practices across the country. Those patients in whom constipation was relieved had a better outcome.

Local anaesthetic has been combined with a proteolytic enzyme derived from mammalian pancreas or papaya in the treatment of acute fissure[65]. In this small uncontrolled study, healing was noted in all patients but all also had stool softener and sitz baths. There was no follow-up after initial healing. Other preparations that are said to promote healing in tissues when applied locally have been investigated in the treatment of acute fissure[66–69], but have not gained widespread acceptance.

Surgical

Récamier[70] in 1838 is widely cited as giving the first description of anal stretch. Since this time its popularity for treatment of anal fissure has waxed and waned. Its use was recommended by Goodsall[51] at the turn of the century and later by Gabriel[56] and others[2,29,71]. Surgeons have been attracted to the procedure by 'its extreme simplicity' and because 'it can be easily performed by relatively junior staff without any special equipment'[2,29]. However, the technique is difficult to standardize and is criticized for causing uncontrolled tearing of the sphincter[72].

The amount of force used, degree and duration of stretch recommended varies between authors, but many have used four fingers inserted into the anal canal for at least 4 min[2,29,50,71,73,74]. Responding to criticism of the imprecise nature of anal dilatation some authors have attempted to standardize the procedure with lengths of string around the fingers limiting distraction, or replacing fingers with a Parks retractor or a balloon so that overstretching and tearing of the sphincters does not occur[73,74]. Comparison of the results of anal dilatation is difficult as there is no standard technique and follow-up differs between trials. It seems likely that problems will present with longer follow-up or if the patient is asked about difficulty controlling flatus or soiling of the underclothes rather than incontinence[75]. Patients with acute and chronic fissures often are included in the same treatment group, making healing rates difficult to interpret. Of 16 trials[29,58,71,74–86] examining the use of anal dilatation in the treatment of anal fissure, most reported rapid and effective symptomatic relief following the procedure. Recurrence of the fissure was reported as 2·2–56·5 per cent and tended to be higher with longer follow-up. Disturbance of continence ranged from 0 to 39·2 per cent for incontinence of flatus or soiling of the underclothes, and faecal incontinence was reported in up to 16·2 per cent. Four-finger dilatation was used in ten of these trials; there was widely varying outcome in both the incidence of recurrence and incontinence, highlighting the interoperator variation in performing the procedure as much as the differences in data collection.

Patients who complain of impairment of continence following anal dilatation have low resting anal pressures and low voluntary squeeze pressures[87,88]. Of 12 men who had faecal incontinence subsequent to anal dilatation, 11 were noted to have disruption of the IAS using anal endosonography[87]. Fragmentation of the IAS was seen, rather than a single tear, with disruption of a mean of 153° of the sphincter circumference. In some, the remaining sphincter showed signs of degeneration and an increase of connective tissue. Three of the patients studied also had defects of the external anal sphincter. Nielsen and co-workers[89] performed anal endosonography on 20 consecutive patients 2–6 years after anal dilatation. Two of the study group complained of minor disturbance of continence; both had defects in the IAS. However, 11 of the 18 continent patients had sphincteric defects, four of whom had fragmentation of the IAS. Although these patients did not complain of incontinence they may be at risk if the sphincter weakens with age or further anal surgery is performed[72].

Anal dilatation may also be complicated by bleeding from the fissure requiring later admission, perianal bruising, strangulation of associated prolapsed haemorrhoids, perianal infection, Fournier's gangrene and full-thickness rectal prolapse in elderly women[29,71,74,79,82–84,90,91]. Bacteraemia was noted in 8 per cent of patients having anal dilatation and the use of prophylactic antibiotics in those who are immunosuppressed or have cardiac valve disease or prosthetic valves is advocated[92].

Operations involving the incision of sphincter muscle around the anus have been performed since the early 19th century[25,60]. Until Eisenhammer[22] clarified the anatomy of the anal canal it was believed that these operations divided a part of the external sphincter, when in all probability the IAS was divided[93]. Since this time internal anal sphincterotomy has become one of the most frequently performed surgical procedures with many variations in technique described. Division of the internal sphincter through the base of the fissure in the posterior midline, with or without fissurectomy, was employed for many years[60,94]. However, the sphincterotomy wound is slow to heal in comparison to the wound after lateral spincterotomy and hospital stay is longer[78,95]. Immediate skin grafting of the sphincterotomy wound in an effort to speed healing has not found general acceptance[96]. High rates of soiling of the underclothes after the procedure have been reported[1,78,95,97]. On inspection of the anus a gutter in the posterior midline was seen in up to 28 per cent of patients after midline sphincterotomy. This 'keyhole deformity' caused imperfect closure of the anal canal or trapping of faecal residue which later discharged on to the underclothes. Some authors report that this complication is not observed when the deeper fibres of the IAS are not divided and Mazier[100] believed that there was little problem with keyhole deformity after posterior sphincterotomy[98–100]. However, Mazier's study group consisted of patients presenting with incontinence of any cause and he did not follow up patients after posterior sphincterotomy.

Randomized prospective trials of posterior *versus* lateral sphincterotomy favour the latter[78,95], which was described by Brodie in 1835[25]. Brodie recommended lateral rather than posterior sphincterotomy because of the shorter healing time of the former. Lateral sphincterotomy is now the treatment of choice in anal fissure for many surgeons[101]; it may be performed using an open or a subcutaneous technique and under local or general anaesthesia[102,103]. Both open and subcutaneous methods produce adequate and equivalent falls in anal pressure[104]. One prospective trial comparing the two methods found that hospital stay and pain after operation were less after closed sphincterotomy, although less than half of the patients completed the pain questionnaire[105]. A larger prospective trial[106] found no difference between the two methods in terms of recurrence rate, postoperative complications or short- and long-term impairment of continence. Another recent retrospective study[107] followed up patients who had open or subcutaneous sphincterotomy by questionnaire and found that, while there was no difference in recurrence rate or the need for reoperation between the two procedures, there was more soiling and faecal incontinence in those undergoing open sphincterotomy.

The results of lateral sphincterotomy have been reported from many centres (*Table 1*). Complication rates vary, but the largest studies report impairment of continence in up to 30 per cent of patients. These are reports of results from largely unselected series of patients, although none include reoperation for recurrent fissure. Only one study measured resting anal pressure before operation, but no patients were excluded because of low pressure[104]. Although incising the whole length of the IAS is inadvisable, it is uncertain just how much of the sphincter should be divided; a consensus view appears to be to divide the sphincter for the length of the fissure. It has been suggested that the incidence of recurrence and alteration of continence is not affected by length of the sphincterotomy[1]. However, a prospective study[121] of the extent of IAS division at sphincterotomy using anal endosonography suggested that more of the IAS than intended was divided, especially in female patients. A further endosonographic study[122] examining patients with persistent anal fissure after lateral internal sphincterotomy found that in five of seven patients no defect could be detected in the IAS, although defects in the external anal sphincter were observed at a site consistent with the position of the previous sphincterotomy. The American Society of Colon and Rectal Surgeons[101] recommend caution before performing internal sphincterotomy in patients with diarrhoea, irritable bowel syndrome and diabetes, and in the elderly. In view of the above reports, the authors recommend that before further surgery for fissure is contemplated, resting anal pressure should be recorded and the anal sphincter complex visualized by endoanal ultrasonography in those patients with recurrent fissure after previous surgery, and in women who have previously undergone episiotomy or suffered a third-degree tear during labour.

Sphincterotomy may be performed under local or general anaesthesia. Despite reports of higher recurrence rates after procedures performed under local anaesthesia, several authors advocate performing sphincterotomy as an outpatient procedure and describe good results[111,112,117,123].

Several comparisons of internal sphincterotomy with anal dilatation in the treatment of anal fissure have been made. Two studies on successive consecutive groups of patients were reported from Leeds, the first group treated by sphincterotomy[1], the second by anal dilatation[71]. Recurrence of the fissure was seen twice as often after dilatation than after sphincterotomy; however, minor defects of continence were observed more frequently after sphincterotomy. Goligher[2] subsequently recommended anal dilatation as initial treatment for fissure with

Table 1 Results of lateral sphincterotomy for anal fissure

Reference	Year	No. of patients	Technique	Incidence of incontinence (%)	Complications (no. of patients)	Length of follow-up	Recurrent/unhealed fissures (%)	Median time to healing

IAS, internal anal sphincter

sphincterotomy reserved for recurrence. However, posterior midline sphincterotomy was performed in these patients and many of those found to have impaired continence were seen to have a keyhole deformity of the anus. Later, on changing to lateral sphincterotomy, impairment of continence became less than was observed following dilatation and this method was recommended as the initial treatment of choice[2,108]. Retrospective follow-up by questionnaire in another group of patients found that recurrence of pain and problems of incontinence were seen less often after lateral sphincterotomy[82].

A prospective randomized controlled trial comparing the two methods was performed in 66 patients by Fischer and Hamelmann[85]. After 2 years of follow-up the incidence of incontinence was significantly greater after dilatation. No statistical difference in the recurrence rate was observed. Further prospective randomized trials have demonstrated a lower recurrence rate and fewer complications following lateral sphincterotomy[79,83,86]. Two other prospective randomized controlled trials have not shown any difference between the two methods[80,81]. Marby *et al.*[84] reported that improvement was seen in 93 per cent of patients by 4 months after anal dilatation compared with 78 per cent after lateral sphincterotomy, and that recurrence was seen in significantly fewer patients randomized to dilatation. However, in this trial sphincterotomy was performed under local anaesthetic and anal dilatation under general anaesthetic. The same group reported later[123] that 53 per cent of fissures recurred after treatment by lateral sphincterotomy under local anaesthetic, compared with only 3 per cent after the same procedure performed under general anaesthesia. It may be that inadequate sphincterotomy was performed under local anaesthesia.

Laser instruments have been used to perform internal sphincterotomy in the place of scissors or a scalpel blade, with no great advantage[124,125]. Advancement flaps have been used to cover the fissure with perianal skin to promote primary healing. A broad based V–Y advancement flap has been used to treat patients who had normal or low resting anal pressure in the presence of anal fissure[126]. Twenty-one patients, the majority having had previous lateral sphincterotomy or obstetric trauma, were treated by V–Y advancement flap with no flap necrosis or disturbance of continence. All fissures healed after treatment by this method. A prospective randomized trial to compare a rhomboid advancement flap with lateral sphincterotomy was performed with 20 patients in each group[127]. All fissures healed after sphincterotomy whereas three of 20 failed to heal after treatment by advancement flap, two of which were subsequently successfully treated by sphincterotomy. Advancement flaps may have a role in the treatment of fissures that occur in the presence of low anal pressure where further division of muscle would be undesirable.

Management of anal fissure in Crohn's disease

The management of fissure associated with Crohn's disease is controversial. In a recent series[4] of patients with fissure associated with Crohn's disease there were complications in 13 of 50 patients who remained unhealed after conservative treatment. Six ultimately required proctectomy for sepsis originating from the site of the fissure. Despite this report, the consensus remains that fissures associated with Crohn's disease should be treated conservatively and surgery reserved for the complications which occur in 10 per cent of cases. These include sepsis and fistula arising from the base of the fissure[2,3,128].

Recent innovations

Botulinum toxin is one of the most lethal of biological toxins; it acts rapidly and strongly binds to presynaptic cholinergic nerve terminals[129]. The toxin is internalized and inhibits calcium-dependent exocytosis of acetylcholine[130]. Paralysis occurs within a few hours. Transmission of neuromuscular impulses resumes after the growth of new axon terminals and clinical weakening of muscle is seen for 3–4 months. Botulinum toxin has been used to weaken striated muscle in the treatment of disorders such as blepharospasm and spasmodic torticollis; it may also weaken smooth muscle in the gastrointestinal tract[129,131–134].

Small uncontrolled trials using botulinum toxin to treat anal fissure have been reported[135–137]. Jost and Schimrigk[135,136] treated 12 patients with chronic anal fissure and increased basal sphincter tone who had not responded to conservative treatment with 0·1 ml diluted botulinum toxin 50 units/ml injected into the external sphincter on either side of the fissure. Eight patients reported that they were free from pain on the first day after injection. Manometry performed on day 5 showed a reduction in maximum voluntary squeeze pressure. At 3 months the fissure was healed in ten of 12 patients. Brief episodes of incontinence have been reported in three of 50 patients so far treated. Five of 26 women have developed perianal thrombosis after injection; this complication has not been noted in men[138].

Gui and colleagues[137] injected botulinum toxin of the same strength as above into three sites in the internal sphincter of ten patients with chronic anal fissure. Pain was absent in five patients and reduced in four at first review at 1 week, and had disappeared at 1 month in seven of ten patients. Resting anal pressure was significantly lowered compared with pretreatment values, while maximum voluntary squeeze pressure was unaffected. Healing was seen in eight patients at 2 months. Two relapsed; one was successfully treated with further botulinum toxin and the other requested surgical sphincterotomy. One patient reported a brief episode of faecal incontinence following treatment.

The site of action of botulinum toxin remains unclear. The fall in resting pressure whilst squeeze pressure remained unchanged after injection into the IAS suggests that the toxin may be acting by weakening the IAS with no effect on the external sphincter[137]. However, injection of toxin into the external anal sphincter leads to similar healing rates with a reduction in maximum squeeze pressure. No mention of the change in resting pressure is made by Jost and Schimrigk. As the external anal sphincter consists of skeletal muscle, it may be postulated that this weakening of the external sphincter occurs via the effect of botulinum toxin on cholinergic neurones. However, acetylcholine has an inhibitory effect on the IAS and blockade of its release by botulinum toxin would be expected to cause an increase in anal tone[8]. Botulinum toxin has also been seen to antagonize responses to noradrenaline but not to affect NANC-mediated responses to EFS in guinea pig ileum; it may be that NANC neurotransmitters act unopposed on the IAS after injection of botulinum toxin[139]. What significance the weakening of the external anal sphincter has in healing chronic anal fissure remains controversial and long-term results are not yet available.

There is strong evidence that nitric oxide plays a major role in mediating the relaxation of the IAS[11,14,16]. Exogenous organic nitrates are degraded by cellular metabolism releasing nitric oxide[140]. Sublingual nitroglycerin spray was found to reduce the resting anal pressure for a short period of time but with unacceptable side-effects[141]. Guillemot and co-workers[142,143] reported that topical nitroglycerin ointment rapidly reduced the resting pressure in the upper anal canal in normal subjects and patients with constipation. Basal pressures did not return for a mean of 50 min but a wide variation in the duration of action of the nitroglycerin was observed between patients. No effect on anal resting pressure was observed using a placebo, although the trial was not blinded. Loder *et al.*[144] applied glyceryl trinitrate (GTN) 0·2 per cent ointment to the anoderm of ten patients presenting for physiological assessment of a variety of anal disorders including one with anal fissure. A significant decrease in maximum anal resting pressure was observed by 20 min after application of the ointment which was sustained for at least 9 h after application. These results were confirmed in a small placebo-controlled trial involving patients with constipation, soiling or haemorrhoids.

Topical nitrates have been used in the treatment of acute and chronic anal fissure as well as thrombosed external haemorrhoids[145–148] Eighty-three per cent of acute fissures were healed after 2 weeks of treatment with nitroglycerin 0·3 per cent ointment in a small pilot study, although a high-fibre diet, supplements of phyllium seed and sitz baths were also used[147]. Later results from the same centre reported only nine of 30 patients with acute fissure healed after 2 weeks' treatment on the above regimen, but 23 of 30 by 8 weeks[147]. In both studies a significant reduction in pain, as assessed by linear analogue pain score, was observed within 5 min of application of the ointment and after defaecation. Sixteen patients with chronic anal fissure were treated with isosorbide-dinitrate (ISDN) 1 per cent applied five to six times daily[145]. A significant fall in maximal anal resting pressure was observed within 5 min of application of ISDN; this was sustained for a median of 39 min. Blood flow to the anoderm was assessed using laser Doppler flowmetry and showed a significant and sustained increase compared with pretreatment values. Anal pain was abolished in all patients after 10 days of treatment. Chronic fissures were healed in nine patients after 6 weeks of treatment and in 15 of 16 after 12 weeks. Topical GTN ointment applied twice daily cured 18 of 21 patients with chronic anal fissure after 6 weeks[149]. Previous surgery for anal fissure had been performed in three of the study group, all of whose fissures healed and who therefore avoided further surgery. Little or no fall in maximal anal resting pressure after the application of GTN was observed in patients whose fissure did not heal, including one patient with Crohn's disease.

Many experience mild transient headache when using topical nitrate preparations and an anal burning sensation has also been reported; however, there has been no report of incontinence during treatment[143,145,147]. It has been suggested that those with chronic anal fissure may have a reduced sensitivity to topical GTN ointment and that tachyphylaxis may develop, but this has not yet proved to be a problem in practice[150].

Prospective, placebo-controlled trials and long-term follow-up to assess the recurrence rate of fissures are now needed to evaluate further this method of treatment; this new non-surgical therapy for anal fissure seems promising.

Association of Surgeons of Great Britain and Ireland

The Annual Scientific Meeting of the Association of Surgeons of Great Britain and Ireland was held in Glasgow on 22–24 May 1996 under the Presidency of Professor Sir Miles Irving. The abstracts of the oral and poster presentations of the original work presented at the meeting were published (a new venture) in a BJS Supplement which accompanied the June 1996 issue of the Journal. A record number of manuscripts of full papers describing work presented in Glasgow have been received by the Journal, and the Editors are pleased to report that the 28 accepted articles that follow also represent a record total.

Intestinal barrier dysfunction in clinical and experimental obstructive jaundice and its reversal by internal biliary drainage

R. W. PARKS, W. D. B. CLEMENTS, M. G. SMYE*, C. POPE, B. J. ROWLANDS and T. DIAMOND

*Departments of Surgery and *Clinical Biochemistry, The Queen's University of Belfast, UK*
Correspondence to: Mr R W Parks, Department of Surgery, Institute of Clinical Science, Grosvenor Road, Belfast BT12 6BJ, UK

Intestinal mucosal barrier function in obstructive jaundice was assessed in an animal model and in patients. The effect of internal biliary drainage in patients was also examined. Bile duct ligation for 1 week in the rat resulted in significant bacterial translocation (in seven of 12 animals following ligation *versus* none of the sham-operated controls, $P<0{\cdot}01$). Intestinal permeability, measured by the urinary recovery of orally administered polyethylene glycol, was also significantly increased (+66·2 per cent for ligation *versus* −11·6 per cent for sham, $P<0{\cdot}01$). A prospective study was performed on 33 patients with obstructive jaundice undergoing internal biliary drainage, and results were compared with those in six non-jaundiced patients undergoing laparotomy or endoscopic retrograde cholangiopancreatography and in 11 healthy volunteers. The lactulose : mannitol ratio was used as an intestinal permeability index. Mean(s.e.m.) intestinal permeability assessed before operation was significantly increased in jaundiced patients compared with control patients (0·050(0·010) *versus* 0·016(0·003), $P<0{\cdot}005$). The mean(s.e.m.) lactulose : mannitol ratio in the healthy volunteers was 0·020(0·003), which was similar to that in control patients. In the jaundiced group of patients the intestinal permeability index fell to within normal levels after 28 days of internal biliary drainage (0·050 before operation *versus* 0·021 at 28 days, $P<0{\cdot}02$). These data indicate that intestinal barrier function is impaired in obstructive jaundice and that this impairment is reversed by return of bile to the gastrointestinal tract.

Jaundiced patients undergoing invasive diagnostic and therapeutic procedures are prone to septic complications and renal impairment[1–4], which contribute to postoperative mortality rates varying from 9 to 27 per cent[5,6]. The pathophysiological mechanisms responsible are not fully understood but increased permeation of intestinal bacteria and endotoxins into the portal circulation and impaired Kupffer cell phagocytic function are implicated in the development of these problems[7,8]. In 1959 Fine *et al.*[9] introduced the concept of gut-origin sepsis, in which it was hypothesized that intestinal barrier dysfunction results in the passage of bacteria and their toxins from the lumen to normally sterile extraintestinal sites. This process has been termed bacterial translocation[10] and is demonstrated by culturing bacteria from the mesenteric lymph node complex, liver, spleen or blood in animal models, or from a mesenteric lymph node, serosal scraping or blood in humans.

Bacterial translocation thus provides a method of assessing intestinal barrier function. A significantly higher incidence of septic complications has been described in patients who had bacterial translocation at the time of laparotomy compared with that in those who did not (28 *versus* 11 per cent)[11]. Another method for assessing the integrity of the mucosal barrier, and thus a test of intestinal barrier function, is to measure intestinal permeability. Increased permeability implies functional impairment of the intestinal mucosal barrier and has been shown in burned patients to be a significant risk factor for the development of sepsis[12,13].

The aim of these studies was to investigate the concept of gut-origin sepsis in obstructive jaundice by measuring intestinal barrier function, using the above methods, in an animal model and in patients. In addition, the effect of internal biliary drainage on intestinal permeability was assessed in the clinical setting.

Patients and methods

Animal study

Adult female Wistar rats (250–300 g) underwent common bile duct ligation and division ($n=12$) or sham operation ($n=12$) by means of techniques described previously[14]. The incidence of bacterial translocation and changes in intestinal permeability 1 week after these procedures was determined.

Bacterial translocation

Portal blood culture. Portal blood samples (3 ml) were cultured aerobically and anaerobically with the BacT/Alert

---

Paper accepted 4 July 1996

(Oreganon Tecknika, Durham, North Carolina, USA). Blood cultures were monitored continuously for 7 days. Positive blood cultures were plated out on appropriate media and species identified by standard bacteriological techniques.

Homogenization of organs. The mesenteric lymph node complex, spleen and right lobe of liver were removed and placed in preweighed sterile glass bottles containing sterile prereduced brain–heart infusion (BHI). The bottles were reweighed and tissue homogenates prepared in 2 ml BHI with sterile mortars and pestles.

Quantitative and qualitative culture. Aliquots (0·1 ml) of each of the homogenates were cultured on blood agar, chocolate agar, McConkey agar, prereduced tryptone soya agar and blood agar containing neomycin 75 μg/ml. Plates containing the latter two media were placed in an anaerobic cabinet. A further 0·2-ml aliquot was placed in cooked meat broth and plated out on the standard agar plates the following day. All plates were incubated at 37°C. After the appropriate incubation periods, individual colonies were identified and quantified as colony-forming units (c.f.u.) per gram of tissue using the formula:

$$\text{c.f.u. per g tissue} = N \times D \times 2 \times 10/W$$

where N is the number of colonies on the plate, D is the dilution inoculated on the plate, W the weight of the specimen in grams, 2 for the 2-ml BHI, and 10 for the 0·1-ml inoculum.

Intestinal permeability

Intestinal permeability was measured by calculating the percentage change in the 24-h urinary recovery of orally administered radiolabelled polyethylene glycol 4000 ([^{14}C] PEG 4000) given 1 week before and 1 week after operation. PEG 4000 was used as it is a macromolecule whose size mimics that of antigenic substances, such as endotoxin. Radiolabelled PEG solution (1·0 ml) containing 0·142 g PEG per ml (BDH Chemicals, Poole, UK) and 1·1 μCi/ml of [^{14}C]PEG 4000 (Amersham International, Little Chaffont, UK) was administered to each animal by gavage tube[15] The animals were then placed in metabolic cages and the urine was collected for 24 h. Aliquots (0·5 ml) of the collected urine were placed in scintillation vials and 2·5 ml emulsifying scintillation fluid (Aquasafe 300 Plus; Zinsser Analytic, Maidenhead, UK) was added. The vials were placed in a scintillation counter and counts obtained for each vial. The amount of radiolabelled PEG excreted in 24 h was calculated and expressed as a percentage of the total administered dose. Each animal acted as its own control and the percentage change in intestinal permeability from the preoperative value to 1 week after operation was subsequently determined.

Clinical study

A prospective study was performed on 33 consecutive patients with obstructive jaundice (bilirubin concentration greater than 100 μmol/l) undergoing internal biliary drainage as a definitive therapeutic procedure by surgical ($n = 9$), endoscopic ($n = 11$) or percutaneous ($n = 13$) means. The aetiology of the biliary obstruction is shown in *Table 1*. Of patients who had surgical intervention, six had choledocholithiasis and underwent open cholecystectomy with exploration of the common bile duct and three had malignant biliary obstruction. Of the latter group, one had a Whipple procedure and two had biliary bypass procedures performed without resection. Six non-jaundiced patients undergoing laparotomy ($n = 5$) or diagnostic endoscopic retrograde cholangiopancreatography (ERCP) ($n = 1$) and 11 healthy volunteers were also studied. All patients received 1·5 g cefuroxime immediately before the intervention. Systemic or oral antibiotics were not administered routinely following intervention, but were administered if clinically indicated. Each patient was studied on the day before therapeutic intervention and on days 1, 7 and 28 afterwards. Routine liver function tests were performed and intestinal permeability was measured.

Table 1 Aetiology of obstructive jaundice

	Surgery ($n = 9$)	PTC ($n = 11$)	ERCP ($n = 13$)
Choledocholithiasis	6		7
Pancreatic carcinoma	2	5	2
Cholangiocarcinoma	1	6	2
Secondaries in porta hepatis		1	
Sclerosing cholangitis		1	

PTC, percutaneous transhepatic cholangiography; ERCP, endoscopic retrograde cholangiopancreatography

Intestinal permeability

Intestinal permeability was assessed by measuring the urinary excretion of orally administered lactulose and mannitol. This dual sugar absorption test eliminates the effect of variables, such as gastric emptying, intestinal transit, intestinal dilution, bacterial degradation and renal function, as each of the test molecules acts as an internal marker for the other and therefore provides a specific index of intestinal permeability[16,17]. Although the exact pathways used by the probes is still under debate[18], it is thought that mannitol is absorbed transcellularly via the aqueous pores in the cell membrane and is dependent on total absorptive surface area, whereas lactulose is absorbed paracellularly, via the tight junctions and extrusion zones at the villus tips[17]. An increase in lactulose absorption therefore reflects increased intestinal 'leakiness' and intestinal barrier dysfunction, resulting in a raised lactulose : mannitol ratio. After an 8-h fast, the test solution (10 g lactulose and 5 g mannitol dissolved in 50 ml distilled water) was taken orally. Before administration, the bladder was emptied and a pretest sample of urine taken. Subsequently, all urine was collected for a 6-h period. The volume of urine collected was measured and aliquots of this and the pretest sample were stored at − 20°C until assayed. The concentrations of lactulose and mannitol were measured enzymatically by reduced nicotinamide adenine dinucleotide (phosphate)-linked enzymatic assays, modified from techniques described by Northrop *et al.*[19] and Lunn *et al.*[20] respectively, using a Cobras Fara centrifugal analyser (Roche Diagnostics, Welwyn Garden City, UK). Interference from glucose in the lactulose assay was overcome by incubating the sample with glucose oxidase and catalase for 3 h at 37°C before lactulose analysis[21]. Excretion of both substances was corrected by subtraction of baseline values determined on the pretest samples The amount of lactulose and mannitol excreted was calculated as a percentage of the administered dose and intestinal permeability was expressed as the lactulose : mannitol ratio

Statistical analysis

Non-parametric statistical analysis was employed throughout and significance accepted at the 5 per cent level.

Results

Animal study

Significantly raised bilirubin levels were present in rats 1 week after bile duct ligation compared with those in sham-operated controls (258·4 *versus* 5·8 μmol/l; $P < 0·0001$, Mann–Whitney U test).

Bacterial translocation was demonstrated in seven of the 12 jaundiced rats compared with none of the sham-operated animals ($P < 0·01$, Fisher's exact test). In all seven cases in which translocation occurred, *Escherichia coli* was cultured from the mesenteric lymph nodes. In addition, one animal also had Gram-positive bacilli cultured from the mesenteric lymph nodes.

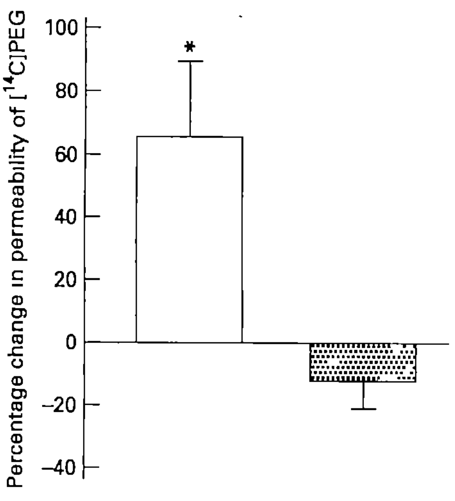

Fig. 1 Mean(s.e.m.) percentage change in intestinal permeability to radiolabelled polyethylene glycol ([^{14}C]PEG) 1 week after bile duct ligation (☐) or sham operation (☐). *$P<0{\cdot}01$ (ligation *versus* sham, Mann–Whitney U test)

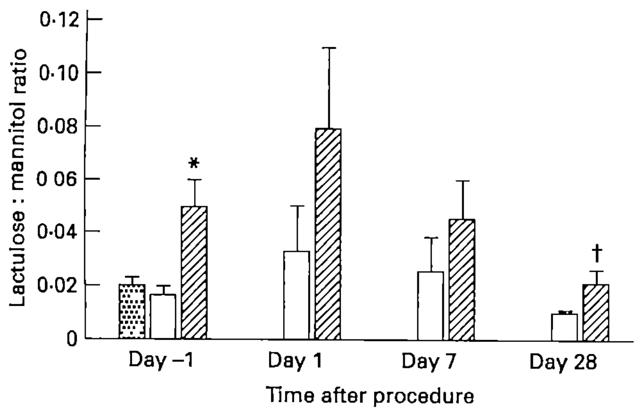

Fig. 2 Means(s.e.m.) lactulose mannitol ratio in jaundiced (▨) and non-jaundiced (☐) patients before and after intervention. ☐, Volunteers. *$P<0{\cdot}005$ *versus* control patients (Mann–Whitney U test); †$P<0{\cdot}02$ *versus* day −1 (Wilcoxon signed rank test)

There was a significant increase in mean intestinal permeability in bile duct-ligated animals compared with sham-operated controls (+66·2 *versus* −11·6 per cent; $P<0{\cdot}01$, Mann–Whitney U test) (*Fig. 1*). There was no significant difference in the percentage change in intestinal permeability between animals demonstrating bacterial translocation and those that did not ($P=0{\cdot}53$, Mann–Whitney U test).

Clinical study

The mean serum bilirubin concentration in jaundiced patients before therapeutic intervention was significantly higher than in control patients (250·2 *versus* 9·7 μmol/l; $P<0{\cdot}0001$, Mann–Whitney U test). After therapeutic intervention the mean serum bilirubin level in jaundiced patients was progressively lower at each of the time points studied, and by day 28 postprocedure fell to within the normal range (156·4 μmol/l on day 1 *versus* 66·9 μmol/l on day 7 *versus* 17·3 μmol/l on day 28).

The mean(s.e.m.) lactulose : mannitol permeability index in 11 normal healthy volunteers (0·020(0·003)) was not significantly different from that in the control group of patients (0·016(0·003)). However, the mean(s.e.m.) lactulose : mannitol ratio for patients with unrelieved obstructive jaundice (0·050(0·010)) was significantly higher than that of control patients studied before operation ($P<0{\cdot}005$, Mann–Whitney U test). There was no significant difference in the mean intestinal permeability index between the subgroups of jaundiced patients before intervention, but each was significantly higher than that in control patients (surgical 0·093 *versus* ERCP 0·036 *versus* percutaneous transhepatic cholangiography 0·040; $P<0{\cdot}05$, Mann–Whitney U test). The lactulose : mannitol ratio in patients with jaundice returned to normal by day 28 after intervention and was significantly less than on the day before the procedure ($P<0{\cdot}02$, Wilcoxon signed rank test) (*Fig. 2*). When jaundiced patients undergoing surgical relief of obstructive jaundice were compared with those undergoing non-operative biliary decompression, there was a significant difference in the intestinal permeability index immediately after the intervention. The mean(s.e.m.) lactulose : mannitol ratio in the surgical group was significantly higher (0·209(0·120)) on the first postoperative day than in the non-operative group (0·042(0·012)) ($P<0{\cdot}05$, Mann–Whitney U test) (*Fig. 3*).

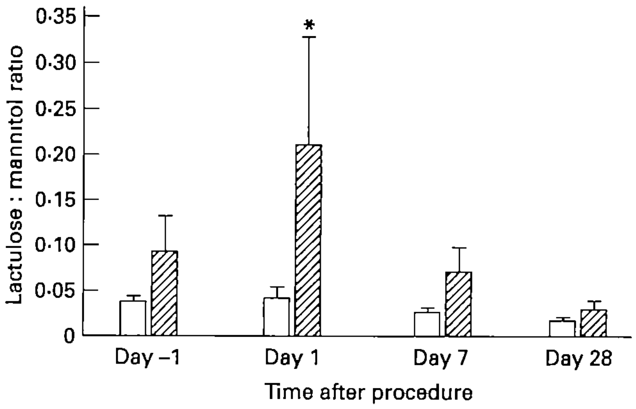

Fig. 3 Mean(s.e.m.) lactulose·mannitol ratio in jaundiced patients before and after surgical (▨) and non-surgical (☐) biliary decompression. *$P<0{\cdot}05$ (surgical *versus* non-surgical, Mann–Whitney U test)

Postprocedural complications occurred in four of the jaundiced patients (acute renal failure in two, urinary tract infection in one, haemorrhage in one). There was no correlation between the occurrence of complications and the initial bilirubin concentration or intestinal permeability index.

Discussion

These studies demonstrate evidence for intestinal barrier dysfunction in obstructive jaundice. Significant bacterial translocation and significantly increased intestinal permeability were demonstrated following experimental biliary obstruction. In addition, significantly increased intestinal permeability was shown in jaundiced patients. Bacterial translocation following bile duct ligation has been reported by others[22–25]. However, the mechanisms by which bacteria escape from the intestinal lumen remain to be clearly defined. Deitch[26] has proposed three factors that promote this process: disruption of the indigenous gut microecology, physical injury of the gut mucosa and impairment of host immunity.

In a previous study, a quantitative and qualitative disruption of the caecal indigenous microflora associated with significant bacterial translocation following bile duct ligation was demonstrated[27]. Bacterial overgrowth and bacterial translocation following experimental biliary obstruction have also been shown by Deitch *et al.*[22] and Ding *et al.*[24]. Deitch and co-workers also described histological evidence of mucosal injury, with subepithelial oedema involving the ileal villi and lifting of the epithelium from the lamina propria. Morphometric evidence of ileal mucosal injury with reduction in villus height and total mucosal thickness in jaundiced rats has been demonstrated[28]. Furthermore, impaired mononuclear cell function has been demonstrated in jaundiced rats[14,29].

To date, there has been limited evaluation of intestinal permeability in experimental models of biliary obstruction or in jaundiced patients[30]. The findings of significantly increased intestinal permeability in the present experimental study were confirmed in the clinical study in which jaundiced patients had a threefold increase in a permeability index compared with non-jaundiced control patients. These data add further support to the hypothesis of intestinal barrier dysfunction in obstructive jaundice.

Returning bile to the gastrointestinal lumen has been assumed to be of benefit and in animal models has reduced postoperative endotoxaemia[31], renal impairment[32] and mortality[33]. Internal biliary drainage has also been considered to be important in the recovery of mononuclear phagocyte function[34,35]. In addition, Ding *et al.*[36] have shown progressively decreased rates of bacterial translocation following choledochoduodenostomy in jaundiced rats, implying an improvement in intestinal barrier function with internal biliary drainage.

In the clinical situation there is conflicting evidence concerning the benefit of internal biliary drainage. In a large study of patients undergoing surgery for pancreatic carcinoma, Trede and Schwall[37] showed that patients who underwent endoscopic internal stenting before surgery had a reduced incidence of postoperative infective complications, and Smith *et al.*[38] demonstrated improved renal function and fewer surgical complications in patients who had a percutaneous stent to allow internal biliary drainage compared with a control group who had immediate surgery. However, Lai *et al.*[39] reported no improvement in postoperative morbidity or mortality in patients who had preoperative endoscopic drainage for malignant obstructive jaundice compared with those who had no preoperative biliary decompression.

In the present study there was an increase in intestinal permeability on the first postoperative day in both jaundiced and non-jaundiced patients. This increase was more marked in patients who underwent surgical intervention than in those who had non-operative biliary decompression, and this may reflect a further endotoxic challenge to intestinal barrier function through exposure to endotoxin at laparotomy[40]. However, by the seventh postoperative day the lactulose : mannitol ratio had returned to preoperative levels. More importantly, in patients with jaundice the intestinal permeability index continued to fall and after 28 days of internal biliary drainage had returned to normal, reflecting a significant improvement in intestinal barrier function with return of bile to the gastrointestinal tract.

In conclusion, this study demonstrates evidence for intestinal barrier dysfunction following experimental biliary obstruction, with significant bacterial translocation and increased intestinal permeability. There was also significantly increased intestinal permeability in jaundiced patients, which returned to normal after 28 days of internal biliary drainage. This suggests that early return of bile to the gastrointestinal tract may improve intestinal barrier function and reduce the incidence of gut-derived sepsis or other complications associated with endotoxaemia in obstructive jaundice.

Methods to minimize the effect of cold ischaemia on porcine islet isolation were investigated. Forty pancreata were randomized to intraductal collagenase delivery in University of Wisconsin solution (UW) or Hanks balanced salt solution (HBSS) (control) both before and after 65 min of cold pancreas storage. Collagenase was also administered in a specially designed cold storage solution (University of Leicester solution, ULEIC), before cold storage. Median islet yield was significantly greater if the pancreas was distended with collagenase in either UW (21 524 islet equivalents (IEQ) per g) or ULEIC (19 814 IEQ/g) before cold storage, compared with that after distension with HBSS (6924 IEQ/g) following cold storage ($P < 0.05$). Islet fragmentation, islet purification and glucose-stimulated insulin release were not significantly different after collagenase delivery in either UW or ULEIC compared with those after administration in HBSS. It is concluded that porcine islet yields can be improved significantly by intraductal collagenase administration in either UW or ULEIC immediately after excision of the pancreas.

With the current shortage of human organ donors investigators have been forced to find an alternative source of islet donor tissue[1]. Few would disagree that porcine islets are the most suitable based on their similar physiological and anatomical characteristics to human islets[2]. Nevertheless, porcine islet isolation is extremely variable because of the particular fragility of these cells[3].

Many factors account for the inherent difficulties in the isolation of sufficient numbers of porcine islets from pancreas. One of the problems that needs to be addressed relates to the ischaemic tolerance of porcine pancreas before islet isolation, as all organs removed for transplantation are subject to an inevitable period of both warm and cold ischaemia. In an attempt to circumvent the deleterious effects of warm ischaemia on porcine islet isolation, previous investigators have procured the pancreas from a heartbeating donor as a prerequisite to successful islet isolation[4]. With regard to minimizing the damaging effects of cold ischaemia, a number of different approaches have been used. Application of a cold intravascular perfusate[5] of either EuroCollins solution[6], hyperosmolar citrate (HOC) or University of Wisconsin solution (UW) has proved efficacious in reducing warm ischaemia time, and in combination with hypothermic organ storage has improved cold ischaemic tolerance of human pancreas, before islet isolation[7]. However, when applied to the preservation of porcine pancreas, cold *in situ* vascular perfusion has been shown to culminate in very poor islet yields, mainly because of islet disruption[4].

An alternative and simpler approach to enhance hypothermic pancreas preservation, in the absence of cold *in situ* vascular perfusion, may be to deliver intraductal collagenase immediately after excision of the pancreas before cold pancreas storage at 4°C. Studies in rats[8] have shown this technique to improve islet yields with administration of collagenase in Hanks balanced salt solution (HBSS), although HBSS is not a cold storage solution[9]. An improvement on this approach may be to deliver the collagenase in UW, immediately after excision of the pancreas and before cold storage. This procedure is effective in both dogs[10] and rats[10], but has been shown to be deleterious in humans because certain components of UW (e.g. glutathione, allopurinol, hydroxyethylstarch (HES) and the reversed sodium ion to potassium ion ratio) have an inhibitory action on collagenase[11–13]. Furthermore, porcine studies have been anecdotal[14,15]. The object of this study was to determine the influence on porcine islet isolation of intraductal collagenase administration, in cold storage solutions.

Materials and methods

Study design

Islet isolations were randomized using sealed envelopes to: (1) collagenase in HBSS either in the islet laboratory ($n = 8$) after cold pancreas storage, or in the local abattoir immediately after excision of the pancreas ($n = 8$) before cold storage; (2) collagenase in UW both in the islet laboratory ($n = 8$) and in the abattoir ($n = 8$) and (3) collagenase in a specially designed cold storage solution, University of Leicester solution (ULEIC) (*Table 1*) administered immediately after excision of the pancreas at the abattoir ($n = 8$) (*Fig. 1*).

Organ donors and procurement technique

Forty porcine pancreata were excised from 2–3-year-old Large White sows obtained from the local abattoir (Dawkins International, Congerstone, UK). Each pancreas was subjected to 10 min of warm ischaemia before excision. The splenic lobe (65–100 g) was excised on all occasions. Care was taken not to disrupt the pancreatic capsule or perforate the adjacent duodenum.

Collagenase distension

Each pancreas had intraductal administration of collagenase 1mg/ml in either HBSS[9] (Gibco, Life Technologies, Paisley, UK), UW[16] (Belzer UW-CSS; Du Pont, Wilmington, Delaware, USA) or ULEIC Of those distended in the laboratory (16 in total) each underwent approximately 65 min of cold ischaemia during pancreas transportation in HOC (Travenol, Thetford, UK) at 4°C[17]. Those assigned to early collagenase administration in the abattoir (24 in total) were also transported in HOC after distension of the pancreas with collagenase. The same batch of

collagenase (lot no. 14039526-54; Boehringer, Mannheim, Germany) was used throughout the study. Before distension, excess fat and lymphoid tissue were removed. The pancreas was weighed and the main pancreatic duct was cannulated with an 18-G cannula (Abbocath-T; Abbot Laboratories, Kent, UK) secured by a 2/0 silk tie (Ethicon, Edinburgh, UK). Each pancreas was distended by slow injection of collagenase in solution at 4°C using 2 ml per g pancreas An evenly distended pancreas was obtained by gradual withdrawal of the cannula during infusion, any ductal leaks were immediately clamped with forceps.

Pancreatic digestion

All pancreata were digested by the automated method[3,18] The pancreas was placed in a stainless steel chamber divided by a 400-μm mesh, along with seven 1-cm^3 steel spheres to aid pancreatic dispersion. HBSS at 4°C was circulated through a closed circuit of polyvinyl chloride tubing (COBE Laboratories, Gloucester, UK) by a peristaltic pump (Watson Marlow, Falmouth, UK) set at a rate of 80 ml/min into a heat exchanger (COBE Laboratories) initially at 35°C. The chamber was manually agitated between two and three times per minute. Pancreatic tissue was flushed from the exit port of the steel chamber and then 5-ml samples were taken via a three-way tap and examined under a light microscope (Nikon, Diaphot, Japan) at × 4 magnification in the presence of dithizone (1·2 mmol/l in 5 per cent dimethylsulphoxide-minimal essential media (MEM) and 1 per cent bovine serum albumin (BSA)[19] (Sigma Chemicals, Poole, UK) for identification of 'cleaved' islet tissue devoid of acinar tissue At this point the circuit was opened and the flow rate increased to 120 ml/min. The temperature was adjusted according to visualization of pancreatic tissue within the biopsies to avoid fragmentation and overdigestion as islets were liberated[20]. The digest was collected in 1-litre Duran bottles containing 15 ml new born calf serum (Advanced Protein Products, Brierly Hill, UK) to inhibit further action of collagenase[21] The collected tissue was washed and spun at 600*g* for 2 min and made up to a volume of 100 ml with UW at 4°C Pancreatic digestion was assumed to be complete when no further islet tissue could be seen within the dithizone-stained samples.

Islet quantification

After 30 min of prepurification storage in 100 ml UW[22,23], five samples of 100 μl were taken from the resuspended pancreatic digest and individually placed in bijoux containing 0·9 ml MEM (Northumbria Biologicals, Cramlington, UK). From each of these five bijoux, single 100-μl strips were aspirated and stained with dithizone in a 140-mm petri dish giving a total dilution of 1 : 10 000. The number of islets totally devoid of acinar tissue (cleaved) and the number still attached to acinar tissue (uncleaved) with a diameter greater than 50 μm, within each strip, were counted under a light microscope (× 100 magnification) calibrated with an optical grid (Cell Finder, Leiden, Holland)[7,18]. This allows estimation of the percentage of cleaved and uncleaved islets along with the total number of islets per gram of pancreas. To calculate the total volume of islet tissue and the mean volume of an islet, 200 consecutive islet diameters were recorded from each of the 40 pancreatic digests. The total volume of islet tissue isolated was calculated as the product of the mean volume of an islet and the total number of islets[7,18].

Having calculated the mean islet diameter from 2–3-year-old Large White sow pancreas to be 80 μm using computerized image analysis (Improvision, Coventry, UK)[24], islet yields were corrected to Large White porcine islet equivalents (IEQ) by dividing the total volume of islet tissue by the volume of an 80-μm porcine islet ($0{\cdot}524 \times (80)^3$), assuming that islets are spherical. This correction, therefore, equates to the 150-μm equivalents reported for human pancreata and allows a more accurate assessment of the isolation index[18,24].

Islet purification

A 3-ml sample of the pooled digest was spun at 600*g* for 2 min A 65-μl aliquot of this packed sample digest was placed in duplicate 10-ml test tubes containing 1 ml high-density BSA (Advanced Protein Products). This was then overlaid with a 10-ml continuous linear gradient of BSA by a two-chamber gradient maker containing 5·2 ml low-density BSA and 5·2 ml high-density BSA (5 2 ml in each chamber to allow for losses within the gradient maker) mixed together with a magnetic flea (Hoefer Scientific Instruments, San Francisco, California, USA). The high-density BSA and low-density BSA were 1·103 g/cm^3 and

1·075 g/cm^3 respectively, following dilution with MEM and measurement with a densitometer (Paar Scientific, London, UK). The final osmolarity was corrected to 400 mosmol per kg H_2O for both high- and low-density BSA by dilution with sodium chloride upon titration with a vapour pressure osmometer (Chem Lab Scientific Products, Hornchurch, UK). The two synchronously produced minigradients were centrifuged at 500*g* for 5 min at 22°C to allow the digest to equilibrate at its isodense point on the gradient. Eleven 1-ml aliquots were then aspirated in successive order from the meniscus of each tube. Each aliquot was washed twice with 3 ml MEM and finally resuspended in a further 2 ml[23,25]. They were then sonicated for three periods of 30 s on ice; 1 ml was aspirated for assay of amylase content (Phadebas amylase test kit; Pharmacia Diagnostics, Uppsala, Sweden) and a further 1 ml mixed with 1 ml Ziegler reagent[26] for subsequent enzyme-linked immunosorbent assay (ELISA) (Medgenix-INS-EASIA; Medgenix Diagnostics, Fleurus, Belgium) of insulin content. The cumulative percentages of the insulin and amylase content within the gradient fractions were plotted against density (Cricket Graphs, Malvern, Pennsylvania, USA) to ascertain the percentage amylase contamination of a 60 per cent insulin yield, deemed to be a reasonable yield of islets[22–25].

Islet viability

Following large-scale purification on a COBE 2991 processor (COBE Laboratories)[27] the viability of islets isolated from five pancreata from each of the five different groups was assessed by *in vitro* dynamic incubation[20]. Five groups of ten islets were hand-picked from each preparation using a drawn-out Pasteur pipette, following 48 h of postpurification culture in Hams-F-12 medium[28,29] at 37°C. They were transferred, in as little medium as possible, to 200 μl low-glucose (1·7 mmol/l, prepared by 1 : 3 dilution with balanced electrolyte solution) RPMI (Gibco) prewarmed to 37°C and placed in a 1·5-ml microcentrifuge tube. The islets were then left to incubate in a shaking water bath at 37°C for 45 min. The 200-μl supernatant was then removed and replaced by a further 200 μl low-glucose RPMI for 1 h then high-glucose (25 mmol/l) RPMI for 1 h and finally with low-glucose (1·7 mmol/l) RPMI for 1 h as described previously[20]. The insulin content within the supernatant of each of the final two phases was measured by ELISA. Stimulated insulin release was expressed in microunits per islet per hour, calculated as the difference between insulin content in the high-glucose response and the final low-glucose response[20,28].

Statistical analysis

Results are expressed as median (range). Differences between each of the five groups were analysed initially by Kruskall–Wallis one-way analysis of variance. Comparisons between pairs were then made, where valid, using the Mann-Whitney *U* test with its significance (adjusted for ties) being expressed as a *P* value. In addition, the 95 per cent confidence interval (c.i.) for differences between the groups was reported where appropriate (Minitab release 8.1; State College, Pennsylvania, USA).

Results

Pancreas digestion

Results for the five different groups are given in *Table 2*, and *Figs 2–4*. There were no significant differences between the groups with respect to weight of pancreas (range 59–110 g) and cold ischaemia time (range 48–99 min). The volume of digest differed significantly, with median values ranging from 0·18 to 0·34 ml/g ($P = 0{\cdot}01$). This was mainly attributable to the increased volume of pancreatic digest following administration of collagenase in UW at the abattoir (median 0·34 ml/g), compared with that after conventional collagenase administration in HBSS at the islet laboratory (median 0·18 ml/g) ($P = 0{\cdot}01$; 95 per cent c.i. −0·24, −0·04). This trend also reflects the significantly greater volume of islet tissue ($P = 0{\cdot}01$) and islet equivalents isolated ($P = 0{\cdot}02$). Median values ranged between 3·55 and 11·02 mm^3/g for volume of islet tissue (*Table 2*), and 6924 and 21 524 IEQ/g for islet yield (*Fig. 2*). When collagenase was administered in UW at the abattoir, islet yields were trebled compared with those obtained with HBSS at the islet laboratory (median 6924 *versus* 21 524 IEQ/g; $P = 0{\cdot}02$; 95 per cent c.i. −33 554, −508) (*Fig. 2*). Collagenase administration in ULEIC at the abattoir was also shown to be superior to the conventional method of delivery in HBSS in the laboratory ($P = 0{\cdot}003$; 95 per cent c.i. 6347, 18 867). When collagenase was administered in ULEIC, islet yields were similar to those of collagenase administration in UW at the abattoir (median 19 814 *versus* 21 524 IEQ/g; $P = 1{\cdot}0$; 95 per cent c.i. −11 699, 20 762) (*Fig. 2*). Finally, the differences between islet–acinar cleavage index and mean volume of an islet were not statistically significant (*Table 2*).

Density gradient purification and stimulated insulin release

BSA continuous density gradient purification studies demonstrated a range of median values of amylase contamination at a 60 per cent insulin yield between 9 and

Discussion

It is well established that short periods of cold pancreas ischaemia before islet isolation are deleterious to both yield[30–32] and viability[33] of islets. Even after as little as 3 h of cold pancreas ischaemia, canine islet yields have been shown to be significantly reduced[30]. In an attempt to improve cold ischaemic tolerance of rat pancreas Ohzato *et al.*[8] demonstrated the benefit of early intraductal collagenase administration in HBSS solution at the time of harvesting. Munn *et al.*[10] were the first to describe the technique of collagenase administration in a cold storage solution using a modified UW in both rats and dogs. It was shown that preservation with modified UW and collagenase before islet isolation maintained islet yields for up to 24 h. The results in this study confirm this hypothesis in the pig, in that regardless of the cold storage solution used, islet yields were markedly improved by intraductal collagenase distension immediately after harvesting and before any period of cold pancreas ischaemia.

However, in humans a number of reports have suggested an adverse affect of UW[7,12,13]. Indeed, the authors have reported recently that UW is inhibitory to human but not to adult porcine pancreas digestion[13] and could ideally be used, therefore, as a solvent for early intraductal collagenase administration to ameliorate cold pancreas ischaemic damage subsequent to porcine islet isolation.

Notwithstanding the benefits of UW for porcine islet isolation, it is an expensive and complex solution. Indeed, some of the additives are thought not to be crucial for its success in preservation of liver[34], kidney[35] and pancreas[36]. Studies in this laboratory[13,23,37] have indicated that adenosine, allopurinol, glutathione and the reversed sodium ion to potassium ion are not essential for cold storage of pancreatic tissue. The key components of UW considered to be of benefit are the impermeants raffinose and lactobionate along with the expensive synthetic colloid[38,39] used to reduce cellular swelling. While the role of impermeants is well established, that of HES is less well understood[36]. For preservation of both canine kidneys and pancreas[36] results have been as effective when HES is replaced with cheaper additives such as dextran-40. Studies of porcine islet isolation also support this finding[37]. Moreover, studies of human islet isolation have shown some degree of collagenase inhibition by HES perhaps by altering the configuration of the active site of collagenase[13,40], although porcine islet isolation remains unaffected[13]. ULEIC was therefore designed specially to contain only those components considered beneficial to cold pancreas storage before islet isolation. The main components are lactobionate, raffinose, dextran-40 and a physiological sodium ion to potassium ion ratio.

The findings from this study suggest that UW or ULEIC have no inhibitory action on collagenase digestion compared with controls. No significant difference could be demonstrated between any of the five groups in terms of islet purification or islet viability *in vitro*, although the ultimate assessment of long-term islet viability *in vivo* would be by porcine islet autotransplantation, however, success has rarely been achieved with that model and *in vitro* function was chosen as an end point[41]. In summary, therefore, early collagenase delivery at the abattoir in any solution before cold pancreas ischaemia was necessary for greater islet yields. Significantly better islet yields were achieved with collagenase administered in UW or ULEIC immediately before cold pancreas ischaemia than with the conventional method of collagenase delivery at the islet laboratory in HBSS following cold pancreas ischaemia. The potential benefit of UW and ULEIC before cold pancreas ischaemia may become more apparent following a longer duration of cold ischaemia.

Incidence and nature of bile duct injuries following laparoscopic cholecystectomy: an audit of 5913 cases

M. C. RICHARDSON, G. BELL*, G. M. FULLARTON and THE WEST OF SCOTLAND LAPAROSCOPIC CHOLECYSTECTOMY AUDIT GROUP

*Department of Surgery, Gartnavel General Hospital, Glasgow and *Surgical Unit, Inverclyde Royal Hospital, Greenock, UK*

The rapid introduction of laparoscopic cholecystectomy has been associated with an apparently increased incidence of bile duct injury which has provoked worldwide concern. The true incidence and mechanism of iatrogenic ductal injury during the development of this procedure remain unclear. To assess this, the introduction of laparoscopic cholecystectomy in the West of Scotland has been audited prospectively over a 5-year period. All cases of biliary ductal injury have been independently reviewed. Some 48 surgeons undertaking laparoscopic cholecystectomy in 19 hospitals submitted prospective data between September 1990 and September 1995. A total of 5913 laparoscopic cholecystectomies were attempted with 98·3 per cent completion of data collection. During this period 37 laparoscopic bile duct injuries occurred. The annual incidence peaked at 0·8 per cent and has fallen to 0·4 per cent in the final year of audit. Injuries occurred after a median personal experience of 51 (range 3–247) laparoscopic cholecystectomies in 22 surgeons. Major bile duct injuries occurred in 20 of 37 patients, giving an incidence of 0·3 per cent. Five mechanisms for laparoscopic ductal injury were identified, including tenting, confluence and diathermy injuries as well as the classical and variant classical types. Ductal injuries were discovered at operation in 18 patients with consequent repair giving a good clinical outcome in 17. Contributory factors (severe inflammation, aberrant anatomy and poor visualization) were present in only 13 of 37 cases. This audit suggests that, at least in the introductory period, laparoscopic cholecystectomy is associated with an overall bile duct injury rate higher than that reported previously after open cholecystectomy, although the incidence of major ductal injury is similar. The late downward trend in bile duct injury, however, suggests there may be a prolonged learning curve for this procedure. Improved understanding of the mechanism of injury may lead to yet further reductions in this complication.

Since its introduction in the late 1980s laparoscopic cholecystectomy has rapidly become the procedure of choice in the treatment of symptomatic cholelithiasis[1]. Unfortunately, the obvious advantages for the majority of patients have been somewhat tempered by the apparently increased risk of bile duct injury compared with that of open cholecystectomy[2], for which historical and contemporary series report the incidence of iatrogenic injury at 0–0·5 per cent[3–7]. The bile duct injury rates for laparoscopic cholecystectomy have been reported to be between 0 and 1·2 per cent, with considerable variation between single-centre and multicentre series[8–16]. The true incidence of biliary injury following laparoscopic cholecystectomy remains unclear, however, because of uncertainties in pick-up rates within retrospective series.

Investigation of the nature of bile duct injury following laparoscopic cholecystectomy has suggested that there is a more severe ductal injury pattern than has been recognized in open cholecystectomy[17–26]. As yet, however, a comprehensive classification does not exist and therefore formal description of the type and mechanism of injury remains difficult.

This audit endeavours to give a definitive overview of the incidence and type of laparoscopic bile duct injuries occurring in the West of Scotland. A classification system for mechanism of injury is proposed on the basis of these findings.

Patients and methods

The West of Scotland region serves a population of 2 422 130 people, supplying healthcare in 19 hospitals. These include 15 National Health Service (six teaching, nine district general) and four private hospitals. The West of Scotland Laparoscopic Cholecystectomy Audit Group was established in September 1990, at the inception of this procedure in the region. All consultant surgeons were enrolled into the audit as they undertook their first laparoscopic cholecystectomy; a total of 48 surgeons was involved. This represented all surgeons providing a laparoscopic cholecystectomy service within these hospitals.

Prospective data were submitted by the operating surgeon on all patients undergoing cholecystectomy A standard pro forma including demographic information, operative details and postoperative course was subsequently reviewed by a dedicated research nurse, who validated the data from individual patient case records. Complete audit was assured by review of all operating theatre records within the region[27].

All cases of laparoscopic bile duct injury identified were individually reviewed by the first author. Full casenote and radiological review has been supplemented by frank discussion of the cases with the surgeons involved. Bile duct injuries were defined as iatrogenic trauma to the hepatic ducts or common bile duct. Inadvertent injury to the cystic duct stump or postoperative bile leaks from other sources were not included. For the purposes of this study injuries were subclassified by severity into major and minor injuries (*Table 1*)[28].

Results

A total of 5913 laparoscopic cholecystectomies were performed in the West of Scotland between September 1990 and September 1995. Overall, this constituted 78·6

Paper accepted 30 May 1996

Table 1 Proposed definition of major and minor bile duct injuries

Grade	Description
Major	Laceration of more than 25 per cent of the bile duct diameter
	Transection of the CHD or CBD
	Development of postoperative bile duct stricture
Minor	Laceration of less than 25 per cent of the bile duct diameter
	Laceration of the junction of the cystic duct with the CBD ('buttonhole' tear)

CBD, common bile duct; CHD, common hepatic duct

per cent of the 7525 cholecystectomies performed during this period. Of those attempted laparoscopically, 5091 were completed and 822 (13·9 per cent) required conversion to an open procedure. Data collection and validation is 98·3 per cent complete; there are 101 case sheets outstanding.

In the 5913 attempted laparoscopic cholecystectomies within this audit there were 37 laparoscopic bile duct injuries, with an overall incidence of 0·6 per cent. The annual incidence peaked at 0·8 per cent and has fallen to 0·4 per cent in the final year of audit (*Fig. 1*). Notably, there were no deaths secondary to bile duct injury within this series. However, 26 patients required prolonged hospital admission and 14 required a further operative procedure.

During this period, 22 surgeons incurred a median of 1 (range 1–5) bile duct injuries after a median of 51 (range 3–247) laparoscopic cholecystectomies. The incidence of bile duct injury therefore varied between 0·4 and 4 per cent for the individual surgeons involved. A consultant surgeon was implicated as the primary operator in 27 patients with a consultant-supervised trainee being responsible in the other ten.

Of the bile duct injuries in this series 20 of 37 were considered major (*Table 1*). The incidence of major bile duct injury was, therefore, 0·3 per cent. This group comprised nine major lacerations or transections of the common bile duct, eight severe injuries to common hepatic ducts including three cases of significant trauma to the confluence, one major right hepatic ductal laceration and two late strictures at the level of the cystic duct insertion. A further 17 bile duct injuries were deemed minor, consisting of 'buttonhole' tears and small lacerations. These involved common bile duct in nine patients, common hepatic duct in six and right hepatic duct in two. The pattern of injury is illustrated in *Fig 2*.

Ductal injuries were discovered at the time of laparoscopic cholecystectomy in 18 patients involving seven major and 11 minor injuries. A total of 13 of these injuries involved the common bile duct with a single recognized injury to the common hepatic duct. In two patients with an acutely inflamed gallbladder the confluence of the hepatic ducts was clipped and divided and a further two injuries were caused by inadvertent partial clipping of the hepatic duct whilst clipping the cystic duct.

Delayed identification of bile duct injury occurred in 19 patients; 13 injuries were major and six minor. Within this group only five injuries involved the common bile duct; 14 patients had trauma to the hepatic ducts. Sixteen patients presented with postoperative bile leaks, four in combination with jaundice, and three experienced jaundice alone

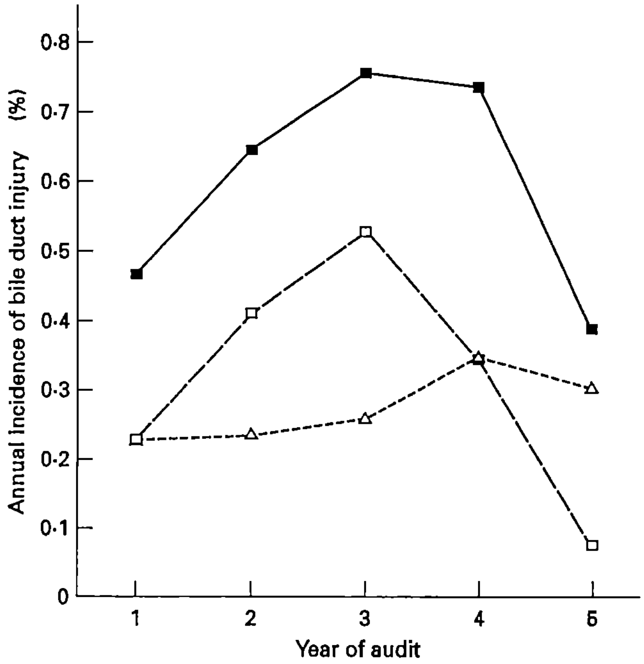

Fig. 1 Annual incidence of laparoscopic bile duct injury. ■, Overall; □, major bile duct injury; △, minor bile duct injury

Contributory factors

Contributory factors that have previously been implicated in laparoscopic bile duct injuries were present in only 13 patients. They included severe inflammation (seven patients), aberrant anatomy (four) and poor visualization (two). No significant contributory circumstances could be identified in the other 24 patients. Although individual surgeons involved had varying views on the exact mechanism of injury, the majority cited misidentification of anatomy as an important contributory factor. Obscured view secondary to bleeding, bile leakage, intervening tissue and suboptimal placement of ports or insufflation played a variable part in structures being incorrectly identified. Adhesion and fatty tissue around Calot's triangle were also quoted as less important factors.

Operative cholangiography was performed on a selective basis by most surgeons; imaging was used in 8·8 per cent of procedures overall. Notably, cholangiography did not play a part in the identification of bile duct injuries in this series. One minor hepatic ductal injury occurred during clipping of the cystic duct following successful cholangiography, when both cystic duct and the adjacent wall of hepatic duct were clipped.

Discussion

The West of Scotland series represents a large comprehensive review of laparoscopic cholecystectomy practice within a geographically defined region. As data collection was prospective, 98·3 per cent complete and subsequently validated by an independent research nurse, it reflects a highly accurate overview of the introduction of this technique.

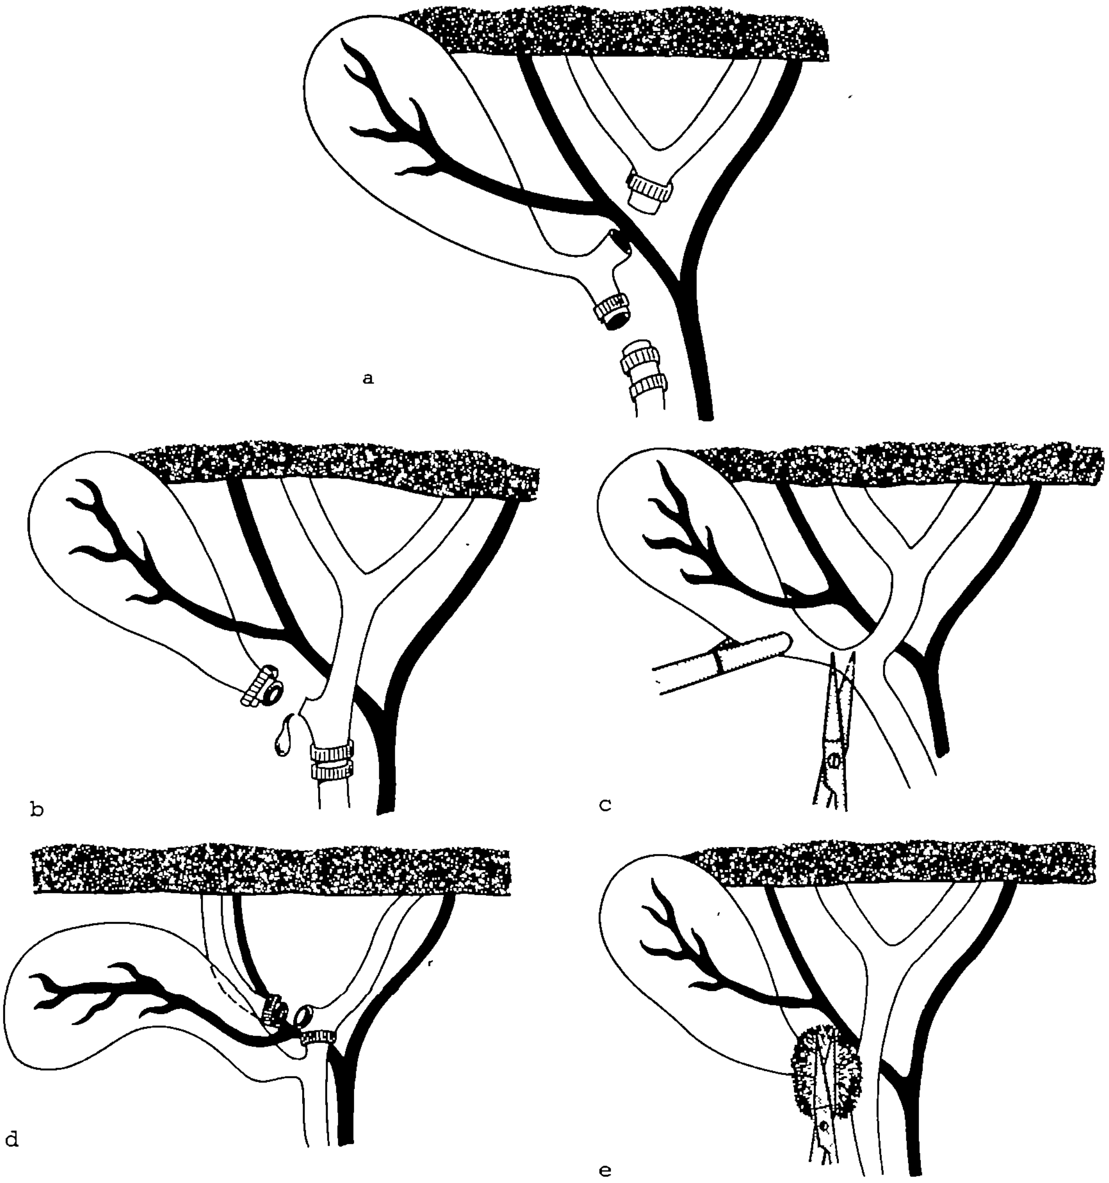

Fig. 2 **a** 'Classical' injury (seven of 37 cases): misidentification of the common bile duct for the cystic duct with resultant clipping and division of the common duct and resection of a segment of common hepatic duct. Underlying right hepatic arterial injury associated. **b** 'Variant classical' injury (three cases): incorrect identification of common bile duct for proximal cystic duct with clipping. Upper cystic duct identified correctly, clipped and divided, leading to a bile leak. **c** 'Tenting' injury (17 cases): lateral traction of gallbladder causes tenting of common duct with loss of angle of interception with cystic duct. Dissection low on cystic duct leads to inadvertent laceration (or clip involvement) of the common duct at this junction. **d** 'Confluence' injury (five cases): misidentification of right hepatic duct for cystic duct. Clipping and division around the confluence results in a high, severe injury. **e** 'Diathermy' injury (five cases): injudicious use of diathermy in Calot's triangle with resultant bile leak (necrosis) or late stricture

The overall conversion rate of 13·9 per cent is somewhat higher than that reported in many previous series[16,29–31] but probably reflects that this audit commenced at the very introduction of laparoscopic cholecystectomy to the region. It is, however, comparable to the overall conversion rates noted in randomized controlled trials and other British series[2,15,32]. By encompassing a broad spectrum of surgeons as they first introduced the technique this series represents the laparoscopic learning period. Although the conversion rate remains relatively constant over the audit period it shows a significant reduction for the more experienced laparoscopic surgeons.

An overall laparoscopic bile duct injury rate of 0·6 per cent in this audit compares unfavourably with an incidence of 0–0·5 per cent for iatrogenic injuries in historical and more recent reviews of open cholecystectomy[3–7]. However, a recent large audit of current cholecystectomy practice from Canada has, in fact, shown a higher incidence of bile duct injury at 2·1 per cent after open cholecystectomy compared with 0·7 per cent after laparoscopic cholecystectomy[16]. This increased bile duct injury rate after conventional cholecystectomy may reflect more complex cases currently being subject to open procedure. Most of the available figures arise from retrospective voluntary reporting and therefore may underestimate the true incidence. Whether the precise definition of bile duct injury used in this study has been rigorously applied in retrospective open cholecystectomy series remains open to question. It may well be that the incidence of bile duct injuries that should be used for comparison is that for major laparoscopic bile duct injuries, which stands at 0·3 per cent in this series, and is therefore similar to that reported at open cholecystectomy. In fact in the final year of this audit the major bile duct injury rate was less than 0·1 per cent.

The incidence of laparoscopic bile duct injury has been reported to be between 0 and 1 per cent[8–14,16] with a wide range in early series being explained by small numbers and a relatively low incidence[13,33,34]. More recently large single-centre cohorts have often demonstrated local expertise and therefore report a lower rate than that seen in this complete regional audit[8,35,36], although a recent smaller but complete study in the UK has suggested an even higher incidence of laparoscopic bile duct injury at 1·2 per cent[15]. Large multicentre series reported previously mainly reflect retrospective review of voluntary data, without accurate validatory mechanisms, and consequently must be viewed with a degree of caution[9,10,12,14,26].

The incidence of bile duct injury in the West of Scotland appears to have peaked at around 0·8 per cent and fallen to 0·4 per cent towards the end of the audit period, showing a delayed trend when compared with previous reports[12,26,30,37]. The suggested short learning curve with clustering of injuries in the first few cases has not occurred. The learning curve in laparoscopic cholecystectomy therefore appears prolonged and correlates with that seen for the open procedure, where the expected danger period lies between 25 and 100 cases[38]. However, as laparoscopic iatrogenic injuries have occurred across the whole spectrum of experience, continued vigilance is imperative.

The bile duct injury pattern after laparoscopic cholecystectomy appears to be more severe than that noted for open cholecystectomy where minor injuries are thought to predominate[17–26]. Based on the proposed classification system, major injuries account for 54 per cent of the total (20 of 37) in this series. However, the incidence of minor ductal trauma (17 of 37; 46 per cent) is higher than has been alluded to in other series, suggesting a more comprehensive pick-up.

Several attempts have been made to classify bile duct injuries in an effort to define the underlying mechanisms although no formal classification system exists. The higher incidence of minor injuries in this audit has altered the overall pattern of injuries seen (*Fig. 2*). Previously most injuries were considered to be 'classical' or 'variant classical' as initially described by Davidoff *et al.*[18]. These types account for only ten of the injuries seen in this series, in which a less severe 'tenting' injury predominated (17 patients). This injury occurred when marked lateral traction was applied to Hartmann's pouch with consequent tenting of the common duct. Loss of the angle of intersection between the cystic duct and common duct led to inadvertent injury when dissection was carried out around the junction.

Although high biliary injuries have been described, little is known about the mechanism by which they occur except for misidentification of ductal structures. In this audit, so-called 'confluence' injuries usually occurred in association with severe inflammation (acute cholecystitis or empyema) and an attempt at retrograde dissection. In these circumstances, the right hepatic duct was identified incorrectly as the cystic duct, with subsequent clipping and division leading to a severe injury around the confluence of hepatic ducts. This mechanism accounted for five of the injuries seen.

Diathermy has been highlighted previously as a cause of iatrogenic injury but was thought to be responsible for only five of the injuries within this audit. Inadvertent use of diathermy within Calot's triangle close to the common duct led to postoperative stricture in two patients and bile leaks from small perforations in the hepatic duct in a further three.

Although contributory factors were found to be present in a minority of cases, the majority of injuries were secondary to misidentification of anatomy. Tenting of the common duct was implicated in most of the injuries, frequently in association with dissection low on the cystic duct. Based on these findings, the authors advocate the following measures to avoid laparoscopic bile duct injury.

Meticulous identification of anatomy is essential, with clear identification of the anatomy in Calot's triangle before clipping of the cystic duct and artery. This is optimized by dissection of the posterior biliary space to free the neck of the gallbladder from the liver bed in conjunction with adequate demonstration of the junction of gallbladder neck and cystic duct (particularly with retrograde dissection).

Lateral traction on Hartmann's pouch is thought to open Calot's triangle and create a sharper angle between cystic duct and common bile duct but, in fact, may distort and conceal this angle by tenting. Therefore, when significant lateral traction is applied, dissection where possible should be close to the gallbladder and high on the cystic duct. If dissection lower on the cystic duct is necessary this should preferably be blunt with minimal use of diathermy in this region and also within Calot's triangle. If any of the above measures are compromised, early conversion to open cholecystectomy is suggested.

Another feature of laparoscopic ductal injuries has been late recognition with consequent increased severity of injury. This audit reports a higher incidence of peroperative identification compared with previous laparoscopic series (18 of 37 injuries) with the suggestion that early repair leads to an improved outcome[26]. There appears to be an upward trend towards earlier discovery and this may reflect increased vigilance secondary to published worldwide concern. Notably, trauma to the common bile duct appears easier to detect than injuries above the cystic duct.

In conclusion, this study suggests that at least in the introductory period the overall bile duct injury rate after laparoscopic cholecystectomy appears higher than that in open cholecystectomy series reported previously. Considering only major bile duct injuries, however, the overall rate is comparable to that of retrospective open cholecystectomy series. The late downward trend in the bile duct injury rate with experience of laparoscopic cholecystectomy suggests there may be a prolonged 'learning curve' in this procedure. Further reductions, approaching the incidence reported at open cholecystectomy, may be possible with greater understanding of the mechanism of injury.

Day-case laparoscopic hernia repair

D. S. EVANS, P. GHANEH and I. M. KHAN

Department of Surgery, Royal Shrewsbury Hospital National Health Service Trust, Shrewsbury SY3 8XQ, UK
Correspondence to: Mr D. S. Evans

Some 114 patients (median age 52 years) underwent laparoscopic hernia repair as a day-case procedure. Twenty-one patients had bilateral and 11 recurrent hernias. Some 113 patients underwent transabdominal preperitoneal mesh repair but one required conversion to open operation. Mean operating time was 24 min for unilateral and 38 min for bilateral repair. In an operating session of 3·5 h, up to five patients (mean 4·4) underwent surgery and as many as seven hernias were repaired. More than 10 per cent of patients were found to have a previously undiagnosed hernia on the opposite side. A total of 111 patients were discharged home on the day of surgery. Major complications included one omental bleed and one small bowel obstruction. Seroma was the commonest minor complication and occurred in 7 per cent of patients. More than 35 per cent of patients needed no postoperative analgesia. To date there has been one recurrence (follow-up range 2–18 months).

Following the successful introduction of laparoscopic cholecystectomy, it was natural that other laparoscopic procedures would be developed. With the introduction of multiple stapling devices in 1992, many surgeons looked to laparoscopic repair of groin hernias.

Laparoscopic transabdominal preperitoneal mesh repairs began in this hospital in June 1992 and during the next 2 years the technique was refined. In June 1994, with experience of nearly 300 procedures and following the opening of a fully equipped and dedicated day surgical unit (DSU), day-case transabdominal preperitoneal mesh repair could be offered.

Patients and methods

Patients under the age of 70 years who were medically fit (American Society of Anesthesiologists grades I and II) and with suitable home circumstances for day surgery were admitted to the DSU. All patients had surgery under general anaesthesia. The operation was done in the Trendelenburg position with the arms by the side. A prophylactic antibiotic was given on induction of anaesthesia.

After establishing pneumoperitoneum with carbon dioxide the abdomen was entered through a transverse supraumbilical skin incision, either with a 10-mm reusable trocar blind or under direct vision using a Visiport (AutoSuture, Ascot, UK) or Optiview (Ethicon, Edinburgh, UK). The anatomy and pathology on both sides was then assessed at laparoscopy. Before insertion of the lateral ports, the abdominal wall was transilluminated to demonstrate the blood vessels[1]. For unilateral repairs the ipsilateral port was at the level of, and 5–7 cm lateral to, the umbilicus while the contralateral port was in the same position laterally but 2–4 cm inferior to the umbilicus. For bilateral repairs, both ports were placed level with the umbilicus.

Under laparoscopic vision the groin peritoneum was incised transversely and anterior to the defect from 2 cm lateral to the internal ring medial to the medial umbilical ligament. Hernia sacs were reduced or transected leaving the distal part of the sac *in situ*. The anatomy was then further defined and a pouch prepared extending from the symphysis pubis medially to at least 2·5 cm beyond the internal ring laterally. Posteriorly the peritoneum was dissected off the cord structures.

Polypropylene mesh, 12 × 7 cm or 15 × 10 cm, was inserted and positioned, with the medial border adjacent to the symphysis pubis and the inferior border placed well posteriorly to ensure complete cover of the myopectineal orifice. The mesh was then fixed in position, three staples were placed in the region of Cooper's ligament with further staples in the rectus muscle and transversalis fascia. No staples were placed posterior to the iliopubic tract. The peritoneum was double breasted and reconstituted by stapling or suturing, care being taken to ensure complete closure. It was particularly important to ensure that the posterior border of the mesh remained in position.

In some cases, to aid closure, the medial umbilical ligament was drawn laterally and stapled. For bilateral hernias, a similar procedure was done and a second mesh used. On completion of the repair, the lateral cannulas were removed and pneumoperitoneum maintained. The port sites were examined for any bleeding which was controlled, if necessary, by diathermy. In the elderly and those with thin abdominal wall musculature the lateral port sites were closed formally. The umbilical port was closed if a direct-vision cutting device had been used for entry.

On completion of the operation bupivacaine 0·5 per cent was injected around the port sites. Patients were allowed to recover and discharged home, usually within 4 h of completion of the operation. They were instructed not to drive for 48 h and not to lift heavy weights for 10 days. They were seen as outpatients after 2 weeks and subsequently contacted by mail or telephone to complete a questionnaire for review.

Results

In 15 months from June 1994, 114 patients underwent day-case hernia repair; all operations were done by a consultant. Median age was 52 (range 20–70) years and 103 patients were men. The procedure was unilateral in 93 patients and bilateral in 21. The majority of the hernias were indirect (*Table 1*) but included recurrent and sliding hernias and a number of patients with inguinoscrotal sacs. Mean duration of operation (skin incision to final stitch)

Table 1 Type of hernia in 114 patients

	n
Inguinal hernia	
Indirect	70
Direct	53
Recurrent	11
Sliding	11
Pantaloon	8
Femoral hernia	3

There were 21 bilateral hernias

Port-site bleed	1
Port-site infection	1
Groin discomfort or pain	16

was 24 (range 15–60) min for unilateral and 38 (range 30–60) min for bilateral repair. During an operating session of 3·5 h, up to five patients (mean 4·4) underwent surgery and as many as seven hernias were repaired.

One patient with an irreducible hernia required conversion to open operation, while in 113 patients laparoscopic repair was completed. Some 111 patients were discharged from hospital the same day. One patient with a minor port bleed was admitted for overnight observation. No active treatment was required and he was discharged the following day. Another patient, in whom a different model of laparoscopic inflator was being assessed, suffered a minor omental bleed and had a minilaparotomy to secure haemostasis. He was discharged 3 days after operation. Two patients were readmitted more than 48 h after operation, one with pain in the groin on the operated side. This settled spontaneously overnight. The other proved to have subacute obstruction due to an internal hernia, secondary to the peritoneal closure. The medial umbilical ligament had been drawn laterally and stapled anteriorly to complete the closure. This had left a pocket with the opening inferolaterally into which small bowel had herniated. The patient had further laparoscopic surgery and the small bowel was reduced. The pocket was closed by suture and the patient then made an uneventful recovery, returning home 48 h after surgery.

Other complications were minor and transient (*Table 2*), the most common being sac seroma in 7 per cent of patients. Recovery was without complication in 84 per cent. To date, there has been one recurrence. This was repaired laparoscopically 1 year after the first operation.

Nine patients were listed for bilateral hernia repair. At operation a further 12 (10 per cent) were found to have a significant contralateral defect which required repair.

No analgesia was taken in hospital after operation. Following discharge no analgesia was necessary in more than 35 per cent of patients. The remainder required oral analgesia for a mean of 2 days. Analgesia requirement was not related to type or number of hernias repaired.

Some 93 per cent of patients were contacted by mail or telephone 2–18 months after operation and answered a questionnaire concerning satisfaction with the procedure, state of the repair and in particular whether there was any groin bulge or discomfort. More than 90 per cent expressed satisfaction with the procedure carried out in the DSU.

Two patients complained of a groin bulge and thought the repair was unsound. Outpatient review, however, showed no sign of recurrence. Some 85 per cent of patients had had no problems after the outpatient appointment held 2 weeks after operation, while the remainder complained of mild discomfort or stiffness.

Discussion

In accordance with the Royal College of Surgeons of England guidelines[2], 54 per cent of all patients under the same consultant undergoing hernia repair in the 15 months reviewed had day-case surgery. The low complication rate and rapid recovery from operation has enabled an increasing number of patients to have day-case hernia repair. The DSU opened in this hospital when there was already experience with nearly 300 transabdominal preperitoneal mesh repairs. The incidence of complications compared favourably with that in other series[3]. In comparison with open techniques operating times were equal if not shorter, the high throughput of cases being attributable to particular individual anaesthetic and nursing staff[4–6].

All types of hernia, including bilateral and recurrent defects, were suitable; the only difficulty arose with a hernia that was irreducible despite attempted reduction with a combined approach of laparoscopic dissection and external manual compression. Some 98 per cent of patients were discharged home on the day of surgery and more than 35 per cent required no postoperative analgesia, irrespective of the type and number of hernias repaired, similar to previous reports[4,7].

More than 10 per cent of patients with an apparent unilateral hernia were found at laparoscopy to have a significant and, in some cases, more pronounced defect on the other side. Others have found unsuspected contralateral pathology in up to 25 per cent of patients[8,9]. Bilateral repair was done under the same anaesthetic, helping to reduce the expense of further admissions. In long-term follow-up after unilateral Shouldice repair[10], 12 per cent of patients developed a contralateral hernia which required repair 3–8 years after the initial operation.

Speed of recovery and analgesic requirement after laparoscopic repair of bilateral hernias were the same as for unilateral hernias; no patient required overnight admission. In contrast, admission to hospital was common for synchronous open repair or alternatively sequential operation 3–5 weeks later was recommended[11].

Follow-up after open operation is usually reported at 6 weeks after surgery by which time many early complications will have resolved and may go unreported. Community-based studies[12] following open hernia repair have documented a complication rate of 28 per cent, up to four times the incidence of complications recorded in the hospital notes.

Although the follow-up is short, the recurrence rate in this series was less than 1 per cent and was similar to that reported previously[13]. Recurrences usually occur within 6 months of operation and are associated with some unrecognized technical problem at the time of surgery, such as rolling up of the mesh, inadequate fixation of the mesh in the region of Cooper's ligament or use of too small a mesh giving inadequate covering of the myopectineal area. The mesh is placed laparoscopically in the same position as in open operations such as those reported by Stoppa *et al.*[14] and Rignault[15]. Long-term results of laparoscopic repair might therefore be similar to those of these open methods.

The main disadvantage of laparoscopic repair is the requirement for general anaesthesia and, in the case of the transabdominal preperitoneal mesh repair, the need to cross the peritoneal cavity. The present results suggest that the operation can be performed successfully in more than 98 per cent of patients. The procedure has proved advantageous particularly for patients with bilateral and/or recurrent hernias and for those wishing to return rapidly to work, sporting activities or caring for dependent relatives[4].

Most patients under the age of 70 years, and some over, are suitable for day-case laparoscopic hernia repair. This reduces the demand for inpatient theatre time, inpatient beds and cost of nursing staff, and will help to meet the demands of the Patient's Charter[16].

General surgery with a special interest in vascular surgery: changing patterns of workload

M. S. WHITELEY, S. B. RAY-CHAUDHURI, J. CORNES, J. A. MICHAELS and R. B. GALLAND

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to: Mr R B Galland

Prospective surveys of workload were carried out during 1989, 1990 and 1995. Analysis of outpatient referrals, inpatients and operations performed over periods of 3 months was undertaken and the changing patterns of general surgical and vascular surgical workload noted. The number of outpatient referrals rose throughout the study period because of a significant increase in the number of patients with both varicose veins and other vascular problems. There was an increase in the number of emergency admissions for vascular disease. The number of patients having general surgical operations fell; there was a corresponding increase in the number for arterial and venous disease. The general surgical component of a general surgical unit with a vascular interest is gradually declining, as increased numbers of patients with vascular problems are being referred and managed.

A survey from the Vascular Surgical Society of Great Britain and Ireland, published in 1992, suggested that only 4 per cent of members were pure vascular surgeons[1], the remainder carrying out a variable amount of general surgery. In Europe as a whole, specialization into vascular surgery is more advanced. Results of a questionnaire in 1988 suggested that in ten of 21 countries vascular surgery was a separate specialty. In the others it remained part of general or cardiothoracic surgery[2].

Patients with arterial disease take up disproportionate amounts of theatre time and inpatient beds compared with their general surgical counterparts[3]. Evidence is accumulating which suggests that increasing numbers of patients with vascular diseases are requiring treatment; it is now accepted that those with acute limb ischaemia are best managed on a vascular unit[4]. There is reluctance on the part of some general surgeons who do not carry out elective aortic aneurysm repair to deal with ruptured aneurysms. More patients may be referred for treatment as people become aware of the possibility of endovascular treatment. The authors have already experienced an increase in the number of patients with arterial disease referred by general practitioners and a corresponding increase in the number of procedures being performed[5,6]. These changes are taking place in the presence of decreasing resources.

The aim of this paper is to define the changing relationship between general surgery and vascular surgery in a district general hospital vascular unit.

Methods

The population of West Berkshire is approximately 450 000. General surgical cover is provided by six consultant surgeons. Before 1995, the department was split over two sites which were amalgamated during the summer of that year at the Royal Berkshire Hospital. Until December 1994 patients with retention of urine and haematuria were admitted to general surgeons; since then they have been admitted directly under the care of urologists.

The vascular unit was established in 1988. It is staffed by a consultant, house officer, shared senior house officer and shared registrar or senior registrar. In addition, staff grade surgeons carried out two waiting list initiative lists each week from 1991[7]. Vascular emergencies were usually admitted to the general surgical unit responsible for emergency admissions, with transfer to the vascular unit on the following day. There was a varicose vein clinic held at intervals of 2 weeks but other outpatient clinics contained a mixture of general and vascular cases, as referred by local general practitioners.

From 1988 to 1990 there was a steady increase in the number of vascular referrals and the number of vascular procedures performed[6]. Excluding varicose vein operations and major and minor amputations, 78 major vascular procedures were carried out in 1988, 114 in 1989 and 144 in 1990. Thereafter the annual number of operations reached a plateau, with a median of 138 (range 137–156) operations annually.

Detailed audits, each over a period of 3 months, were carried out in 1989[3], 1990 and 1995. Data were collected for the same 3-month periods for each year. Thus audits were performed during the time of an increasing vascular operative workload and at the start of, and 5 years into, a steady state. All new outpatient referrals were documented and were designated vascular, general surgical or varicose veins. Diagnoses were noted. Patients with conditions likely to be suitable for minor surgery, which could be carried out under local anaesthetic, were sent directly for operation on reviewing the referral letter. They are excluded from further analysis. Similarly, details were noted of all patients admitted to the unit, including in-hospital referrals and transfers. All operations carried out were also recorded.

Statistical analysis

Statistical comparisons throughout were made using χ^2 analysis and $P < 0{\cdot}05$ was considered significant.

Results

New outpatient referrals (Fig. 1)

The number of patients referred rose by approximately 56 per cent in 1995 compared with the previous two audits. There was an increase in the number with vascular problems noted throughout the study (1990 *versus* 1995: $\chi^2 = 11{\cdot}51$, 1 d.f., $P < 0{\cdot}001$). Similarly, the number of patients with varicose veins increased from 1989 to 1990 ($\chi^2 = 9{\cdot}69$, 1 d.f., $P < 0{\cdot}005$), and 1989 to 1995 ($\chi^2 = 14{\cdot}23$,

Values in parentheses are percentages

1 d.f., $P<0{\cdot}001$). By contrast, the proportion of patients with general surgical conditions fell throughout the study (1989 *versus* 1990: $\chi^2=19{\cdot}37$, 1 d.f., $P<0{\cdot}001$); and 1990 *versus* 1995 ($\chi^2=15{\cdot}46$, 1 d.f., $P<0{\cdot}001$). Despite only one of six clinics being in an outlying hospital (Henley on Thames), 28 (27 per cent) of the 105 general surgical referrals came from that source.

The commonest vascular condition referred, after varicose veins, was intermittent claudication (*Table 1*). There was an increase in the number of patients referred with carotid disease and complex venous problems. The most obvious change in the general surgical referral diagnoses was the virtual disappearance of patients with breast disease.

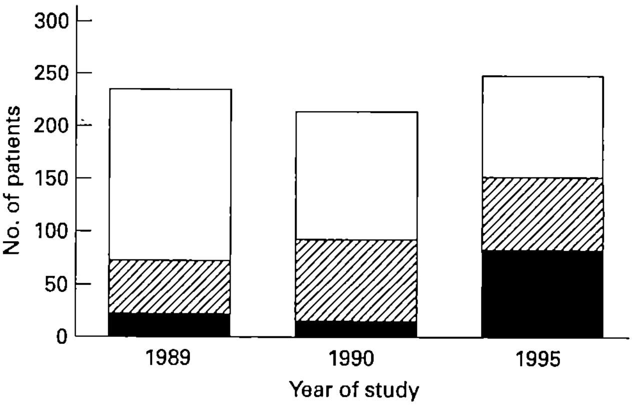

Fig. 3 Number of operations performed. ■, Varicose veins; ▨, vascular; ☐, general

Admissions (Fig. 2)

The total number of patients admitted to the unit did not differ significantly in each of the three audits. By 1995 there were fewer general surgical cases admitted and a greater number of patients with vascular disease. However, the only statistically significant changes involved the increased number of emergency admissions of patients with vascular disease between 1989 and 1990 ($\chi^2=4{\cdot}07$, 1 d.f., $P<0{\cdot}05$), and decreased emergency general surgical cases by 1995 ($\chi^2=15{\cdot}69$, 1 d.f., $P<0{\cdot}001$). The latter coincided with urological emergencies being admitted directly under the care of urologists. Following the introduction of the waiting list initiative in 1991, the number of patients admitted for varicose vein operations rose significantly by 1995 ($\chi^2=62{\cdot}87$, 1 d.f., $P<0{\cdot}001$).

Operations (Fig. 3)

The total number of operations carried out remained fairly constant throughout. The number of vascular operations increased between 1989 and 1990 ($\chi^2=12{\cdot}79$, 1 d.f., $P<0{\cdot}001$). There was a corresponding fall in the number of general surgical operations throughout the study (1989 *versus* 1990: $\chi^2=7{\cdot}42$, 1 d.f., $P<0{\cdot}01$); and 1990 *versus* 1995 ($\chi^2=14{\cdot}98$, 1 d.f., $P<0{\cdot}001$). The impact of the waiting list initiative is shown by an increase in varicose vein operations between 1990 and 1995 ($\chi^2=49{\cdot}00$, 1 d.f., $P<0{\cdot}001$).

The commonest vascular operation performed, after varicose vein surgery, was infrainguinal bypass (19 per cent of total), followed by abdominal aortic aneurysm repair (15 per cent). There was little change in type of operation throughout the three audits other than a reduction in the number of aortofemoral bifurcation grafts and rise in extra-anatomic revascularization for aortoiliac occlusive disease. Carotid endarterectomy became more frequent during the 1995 audit.

Discussion

Although the number of patients seen in the outpatient clinic increased during the study, there was little change in the number admitted to the unit or for operation. However, the proportion with vascular disease is increasing while that of patients with general surgical disease is decreasing. In general, greater resources are needed for an arterial case than for a general surgical case; the authors have shown previously that patients with arterial disease represented only about one-quarter of the caseload but accounted for almost half of the bed occupancy on the unit. Similarly, while arterial operations comprised only 20 per cent of the operating theatre caseload, they accounted for over 30 per cent of available operating time[3]. Others have emphasized the greater complexity of arterial cases compared with general surgical cases[8].

Some aspects of general surgery have been devolved to subspecialists. For example, few patients with breast disease are now referred to this unit; in Reading these patients are nearly all referred to a single surgeon with a special interest in breast disease. Similarly, the advent of laparoscopic surgery has resulted in the elective referral of patients with biliary disease largely disappearing. The appointment of general surgeons with a special interest in day-case surgery will further reduce the general surgical component of the authors' type of unit. The general surgical component has, in fact, largely been maintained by emergency cases, referrals through a general surgical clinic in an outlying hospital and general surgical problems developing in patients with vascular disease.

Organizing the management of vascular emergencies has been the subject of considerable recent debate[9–11]. It is unlikely that even in the largest district general hospital will there be sufficient numbers of surgeons with a vascular interest to maintain an independent vascular rota; adjacent hospitals may cooperate to establish such a rota. It is doubtful that this could be satisfactorily matched with existing general surgical emergency rotas and it seems inevitable that, in time, any vascular surgical emergency rota will separate completely from that dealing with general surgery.

It has been established that good results in vascular surgery are directly related to the number of operations an individual surgeon or institution carries out[12,13]. It has also been shown that those surgeons undertaking more arterial reconstructions achieve a lower rate of major amputation[14,15]. While the benefits to the patient seem clear, a recent survey on career intentions of surgeons in training revealed that few prospective vascular surgeons wanted a practice solely in vascular surgery. Most wished to retain some general surgery, although it was accepted that the majority of the workload would be vascular (M.S. Whiteley, unpublished results). Nevertheless, recent changes in training in the UK leave little doubt that future surgeons will not gain such broad experience as their predecessors did during their training period. Specialization in vascular surgery seems inevitable and this may well result in an increase in the number of pure vascular surgeons in the UK. The demise of 'general' surgery may occur in tandem; this was predicted some years ago[13]. The results of the present study suggest that this demise is not far off.

Changing patterns in aortoiliac reconstruction: a 7-year audit

M. S. WHITELEY, S. B. RAY-CHAUDHURI and R. B. GALLAND

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to: Mr R. B. Galland

A prospective vascular audit was performed in this hospital between 1988 and 1994. There was a substantial increase in the number of vascular reconstructions (78 in 1988; 141 in 1994). Aortobifemoral grafts for occlusive disease comprised 18 per cent of the operations in 1988 and 0·7 per cent in 1994 (95 per cent confidence interval 0·086–0·259). There was a corresponding increase in the number of extra-anatomic grafts (from 3 to 20·6 per cent). There was a threefold increase in the number of percutaneous angioplasties performed for iliac occlusive lesions (14 in 1988; 41 plus 13 iliac stent procedures in 1994). This had no impact on the total rate of surgical intervention for aortoiliac disease, although it probably aided the shift to extra-anatomic reconstruction by dilatation of the donor side. To investigate whether this change is national, rather than local, graft sales figures were obtained from two vascular graft companies; these confirmed a national trend away from aortobifemoral grafting and provide some evidence to support an increase in extra-anatomic bypass grafting.

Aortoiliac occlusive disease requiring intervention can be treated by percutaneous angioplasty or reconstruction. The number of patients who present with vascular disease has increased significantly during recent years[1,2]. A study from Oxford[3] reviewed changes in treatment of aortoiliac disease over 4 years from 1985 to 1988. There was a doubling of the number of patients with aortoiliac disease who required intervention and a large increase in the number of percutaneous angioplasties of the iliac arteries (two in 1985; 34 in 1987). This was associated with a decrease in the proportion of patients having aortobifemoral bypass. There was no change in the proportion of patients who had extra-anatomic bypass grafting.

In 1988 a prospective audit was started to collect data relating to vascular reconstructions performed in this hospital. This database was analysed for a 7-year interval from 1988 to 1994 to define changes in the management of aortoiliac occlusive disease.

Patients and methods

The Royal Berkshire Hospital in Reading serves a population of approximately 460 000. A prospective audit of all vascular reconstructions performed under the care of one general surgeon with a vascular interest was started on 1 January 1988. During this audit the major indication for aortoiliac reconstruction was critical limb ischaemia. Unfortunately the audit did not identify preoperative risk factors but the general impression was of an increasingly elderly and high-risk population.

Numbers of reconstructions for aortoiliac occlusive disease were obtained and displayed as a percentage of the total number of vascular reconstructions performed in that year.

The number of percutaneous angioplasties of the iliac arteries was noted, as was the number of iliac stent procedures. Indications for stent placement included long iliac artery occlusion, asymmetrical stenosis that persisted despite balloon dilatation and bilateral stenosis of common iliac artery origin (requiring 'kissing stents').

In an attempt to identify whether the changes in this hospital were reflected throughout the UK, five companies that manufacture and sell vascular grafts were asked to provide data on any changes in sales of different vascular grafts Two companies responded (Vascutek, Inchinnan, UK; Bard, Crawley, UK). Proportions of each type of graft were calculated from the total number of grafts sold that year and were expressed as percentages. Company figures divided grafts into three categories: bifurcate (aortobifurcated grafts), straight (of any length) and externally reinforced grafts.

Statistical analysis of results was performed using 95 per cent confidence intervals, calculated with the Clintest statistical computer package (Clinical Statistics System version 1.01. Clinical Statistics 1993, UK).

Results

Aortobifemoral grafts

During the first 3 years of the study the proportion of aortobifemoral grafts was constant at about 20 per cent, despite an almost doubling of the vascular workload (from 78 to 144 cases) (*Fig. 1* and *Table 1*). Over the next 4 years there was a steady decrease in the proportion of aortobifemoral grafts. Reductions to 6·5 per cent in 1992 (95 per cent confidence interval (c.i.) 0·020–0·209), 3·6 per cent in 1993 (95 per cent c.i. 0·052–0·234) and 0·7 per cent in 1994 (95 per cent c.i. 0·086–0·259) were all statistically significant.

Extra-anatomic grafts

The extra-anatomic grafts used were predominantly axillobifemoral and femorofemoral grafts. In 1991 there

Paper accepted 18 June 1996

Table 1 Number of aortobifemoral grafts, extra-anatomic grafts and total reconstructions by year

	Year						
	1988	1989	1990	1991	1992	1993	1994
Aortobifemoral graft	14	26	27	21	9	5	1
Extra-anatomic graft	2	3	1	12	5	20	29
Total reconstruction	78	114	144	156	139	137	141

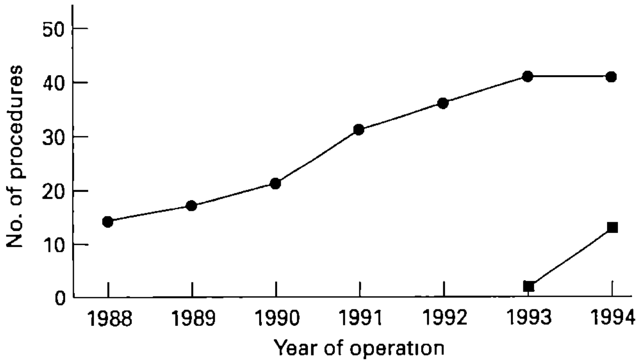

Fig. 2 Number of iliac artery angioplasties (●) and iliac stent procedures (■) from 1988 to 1994

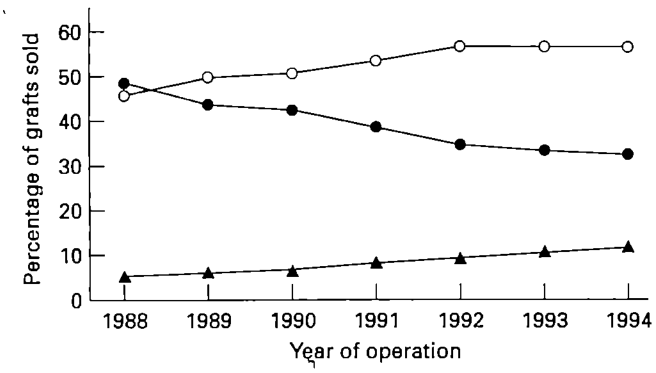

Fig. 3 Trends of graft sales nationally from 1988 to 1994. ●, Bifurcated aortic grafts, ○, straight peripheral grafts; ▲, externally reinforced peripheral grafts

was an increase in the proportion of patients having extra-anatomic grafts to 7·7 per cent but this was not significant (95 per cent c.i. −0·106 to 0·003). This increase mirrored the decrease in aortobifemoral grafts used in the same year (*Fig. 1*). In 1993 and 1994 there were significant increases in the proportion of extra-anatomic grafts used, 14·6 per cent (95 per cent c.i. −0·189 to −0·052) and 20·6 per cent (95 per cent c.i. −0·255 to −0·105) respectively.

Percutaneous angioplasty and iliac stents

The number of percutaneous iliac angioplasties performed rose steadily throughout the years studied from 14 in 1988 to 41 in 1994 (*Fig 2*). Iliac stent procedures were introduced in 1993; 13 were performed in 1994.

Graft manufacturer sales of vascular grafts

Throughout the 7 years studied the proportion of bifurcated aortic grafts sold steadily decreased. This was matched by a steady rise in sales of both straight and externally supported grafts (*Fig. 3*).

Discussion

Aortobifemoral grafting for occlusive vascular disease is very effective[4]. However, it is a major procedure with a mortality rate of approximately 6 per cent and a correspondingly high morbidity rate[5]. Extra-anatomic grafting has a similar mortality rate and lower morbidity rate despite being performed in older and less fit patients[6].

Analysis of operative procedures in this study showed a dramatic decrease in the number of aortobifemoral grafts from 1991 onwards with an increase in extra-anatomic grafts. Femorofemoral crossover grafting for unilateral iliac artery occlusive disease has excellent patency rates (92 per cent cumulative patency at 6 years) with a low early mortality rate (1·3 per cent) and short hospital stay[7]. Even less enthusiastic surgeons agree that femorofemoral grafts provide adequate function and limb salvage in patients who are at high risk or with limb-threatening ischaemia[4]. In the presence of bilateral iliac artery occlusive disease with a localized stenosis in one iliac artery, angioplasty on this side followed by femorofemoral crossover grafting produces acceptable results for limb salvage[8].

Axillobifemoral bypass grafting, once reserved for infected aortic grafts or patients with a 'hostile abdomen', has become an accepted alternative for-bilateral iliac occlusive disease. Primary patency rates of 78 per cent at 5 years have been reported, which are similar to those of aortofemoral bypass surgery[6,9].

The success of percutaneous angioplasty for iliac stenosis and short occlusions has been well documented[10]. Angioplasty combined with endoluminal stenting is used in an attempt to maintain patency in occlusion and recurrent stenosis[11]. However, careful analysis and follow-up of patients undergoing iliac angioplasty reveal 3-year patency rates below those expected from surgical reconstruction[12]. In the presence of critical ischaemia it has been suggested that surgical revascularization or combined angioplasty and operation could be a better option than angioplasty alone[13].

Previous studies from Leicester[1] and Edinburgh[14] have shown that large increases in the number of percutaneous angioplasties carried out make no difference to the number of vascular reconstructions performed. However, the present data have shown a trend away from aortobifemoral grafting towards extra-anatomic grafting. This is facilitated in some patients by dilatation of an iliac stenosis in a donor limb before femorofemoral crossover. Hence percutaneous angioplasty has influenced a changing pattern of reconstruction if not actually decreasing the number required.

Evidence was sought to suggest that this trend may be being repeated nationally. The proportion of different types of graft sold tends to confirm this. The number of bifurcated graft sold has dropped considerably, although these grafts are also used for aneurysm repair. Unfortunately there is no breakdown of what the grafts were used for. Clearly some of the straight grafts could be used for femoropopliteal or other reconstructions. The increased use of straight grafts with a significant decrease in the proportion of bifurcated grafts provides some evidence that there is a national trend away from aortobifemoral bypass grafts.

Prospective study of carotid endarterectomy and contralateral carotid occlusion

A. F. DA SILVA, P. McCOLLUM, T. SZYMANSKA and L. DE COSSART

Audit Committee of the Vascular Surgical Society of Great Britain and Ireland, Department of Surgery, Countess of Chester Hospital, Liverpool Road, Chester CH2 1BQ, UK

Correspondence to: Mr A. F. da Silva

A total of 700 patients who had carotid endarterectomy (CEA) in the UK and Ireland during a 6-month interval between March and August 1994 were studied prospectively. Some 108 patients (15·4 per cent) had a contralateral internal carotid artery occlusion. Previous reports have shown an associated stroke rate of about 10 per cent in these patients. This study assessed complications and outcome for patients undergoing CEA with contralateral internal carotid artery occlusion compared with those without. The indications for surgery were comparable between the two groups although the patients with occlusion had a slightly higher incidence of arrhythmia and stroke. Intraoperative shunts were used in a significantly higher proportion of those with occlusion (83·3 *versus* 64·7 per cent, $P = 0·0001$). The combined death and stroke rate for patients with occlusion was 5·6 per cent compared with 2·4 per cent for the remainder (P not significant). On the basis of the present data, CEA with a contralateral carotid artery occlusion carries only a slight increase in the rate of postoperative stroke and death. This increase was not statistically significant and is lower than that reported previously.

The benefits of carotid endarterectomy (CEA) for symptomatic patients with carotid stenosis greater than 70 per cent are now accepted[1,2]. CEA in patients with contralateral carotid artery occlusion carries a higher peroperative and postoperative risk of stroke[3,4]. Improved results might follow if this high-risk group of patients could be identified and adequate measures instituted to overcome inadequate cerebral blood flow, such as obligatory intraoperative use of a shunt. The objectives of this prospective study were to assess the early outcome and complication rate of CEA in patients with a contralateral internal carotid artery occlusion and compare them with those of patients with no contralateral occlusion.

Patients and methods

A prospective study of CEA was designed in 1994 to examine 30-day outcome for all patients undergoing the procedure under 59 consultant surgeons. Sixty members of the Vascular Surgical Society of Great Britain and Ireland (VSS) were selected randomly to participate in the study. After the initial request for participation, six surgeons did not reply and a further group was recruited in order to obtain at least 500 patients for study. Actual participants represented approximately 50 per cent of known consultant vascular and general surgeons in the VSS who currently perform carotid surgery. A cross-section of surgeons was taken to include university centres, district general hospitals, full-time vascular surgeons and general surgeons with a vascular interest. Participation was entirely voluntary and surgeons were asked to include all patients undergoing carotid endarterectomy within a 6-month period from 1 March 1994 to 31 August 1994.

Although some 28 questions were asked, the main endpoints were death and postoperative stroke at 30 days. Individual pro formas were completed for each patient. No patient-identifiable data were recorded although the centre number was recorded initially until data verification was complete. Data were returned to the VSS office and entered into a customized database (DataEase; Sapphire Solutions, Ilford, UK). After preliminary analysis further specific requests were made for missing information and for details of patients where there appeared to be conflicting information. It was not possible to ensure that all cases were entered by the participating surgeon; however, 15 per cent of the total data was examined by an independent physician and neither extra strokes nor any further carotid endarterectomies were uncovered.

Comparison between discrete variables was made using the χ^2 test. The null hypothesis was rejected if $P < 0·05$ and P values shown are two tailed.

Results

There were 108 patients with contralateral internal carotid occlusion (15·4 per cent of the total series of 700). The male to female ratio was 2·7:1 in patients with an occluded artery compared with 2:1 in those without occlusion. Indications for surgery and risk factors for the two groups are summarized in *Tables 1* and *2*.

Consultant surgeons performed 78·7 per cent of operations in patients with occlusion compared with 80·6 per cent of procedures in those without. Mean hospital stay was 8·1 (range 2–39) days for the former patients compared with 6·9 (range 0–91) days in the latter. Mean operating time was 103·6 (range 20–240) min and mean carotid clamp time 11·2 (range 0–55) min in patients with occlusion. In those with a patent contralateral artery the respective values were 96·1 (range 10–240) min and 13 (range 0–85) min. Shunts were used in 83·3 per cent of patients with occlusion compared with 64·6 per cent of those without ($\chi^2 = 14·47$, 1 d.f., $P = 0·0001$, confidence interval 1·60–4·65). When no shunt was used, the mean clamp time was 28·6 (range 15–55) and 28 (range 1–85) min for patients with and without occlusion respectively. Intraoperative cerebral monitoring included electroencephalography, estimation of stump pressure or transcranial Doppler ultrasonography. Some 65·7 per cent of patients with occlusion had some form of peroperative cerebral monitoring compared with 64·4 per cent of those without occlusion. In patients with occlusion, stump pressure was measured in two of the 18 non-shunted patients compared with 12 of the 90 who had shunts. Completion assessment (such as palpation, continuous-wave Doppler imaging, duplex scanning, angiography or

angioscopy) was done for 89·9 per cent of the patients with an occluded artery compared with 88·8 per cent of those without.

Complications and outcome for the two groups are shown in *Tables 3* and *4*. There were no significant differences in the operative complication rates. Postoperative outcome for the two groups was almost identical. In patients with an occluded contralateral carotid artery, a comparison was also made between the shunted *versus* non-shunted subgroups. The numbers are too small for statistical analysis but are displayed in *Table 5*.

Discussion

There is debate concerning the risk of CEA in the presence of a contralateral occlusion with reported peroperative stroke rate ranging from 3 per cent[5] to 10 per cent[3,4]. The present data disclosed that patients referred for CEA in the UK and Ireland had an overall rate of contralateral carotid occlusion of 15·4 per cent which is similar to reported rates of 15 per cent[6] and 13 per cent[7]. In this study those with occlusion had a significantly higher preoperative incidence of stroke (but not of transient ischaemic attack), and also a higher incidence of diabetes and cardiac arrhythmia which might have indicated a higher surgical risk. This risk was not borne out in the subsequent outcomes. Inadequate collateral blood flow is thought to be a predisposing factor for neurological complications in high-risk patients undergoing CEA. Routine carotid shunting should be highly effective and perhaps even obligatory[3] to overcome this[8]. However, shunt insertion is occasionally difficult and may increase the risk of stroke from emboli[8,9]. This was apparently a view not shared by the surgeons in this study, where the use of shunts was significantly higher in patients with occlusion (83·3 *versus* 64·6 per cent). Although the operative complication rate was higher in patients with an occluded contralateral artery, the difference between the groups was not statistically significant. There was no statistical difference in the postoperative death rates. In terms of peroperative monitoring and completion assessment, the surgeons' practice did not differ between the two groups, suggesting that complication rates and outcome, in what is considered by some a high-risk group, were not affected by availability of peroperative monitoring resources.

A shortcoming of this study is that, to ensure maximum reporting compliance by participating surgeons, a relatively short period of audit was chosen which precludes long-term follow-up of these patients. This study represents the first prospective national survey in Great Britain and Ireland of CEA in patients with contralateral internal carotid occlusion and is valid in its assessment of immediate postoperative outcome. The conclusion from this study is reassuring. The risk for the patient with contralateral carotid occlusion is not significantly higher than that for a patient without occlusion and the continuing practice of CEA in the presence of a contralateral occlusion is therefore supported.

Short note

Carotid endarterectomy: an underutilized means of stroke prevention

The results of the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST) demonstrated that carotid endarterectomy (CEA) was beneficial in symptomatic patients with a stenosis of the internal carotid artery of more than 70 per cent[1,2]. There is evidence that general practitioners are unaware of these trial results[3], and that epidemiologists are reluctant to accept the benefits suggested by these studies[4]. Vascular surgeons feel that CEA should be purchased and performed[4], and that underperformance of CEA diminishes the potential of the operation as a means of stroke prevention.

In the UK and North America the stroke rate is similar[5]. In the UK in 1991 the estimated rate of CEA was 24 per million per year[6]. In the USA the rate was 15 times higher at 360 per million[6]. Epidemiological studies suggest that 160 patients per million have a greater than 70 per cent symptomatic internal carotid artery stenosis that is amenable to surgery. This figure is derived from an incidence of first transient ischaemic attack (TIA) of 600 (range 350–3000) per million population[5,7], 20 (range 6–30) per cent of patients with TIA having ipsilateral carotid artery disease amenable to surgery[8–11], and only one-half to two-thirds of patients fit for surgery[11,12]. This gives 80 patients with TIA per million population. There is a similar number of patients with non-disabling stroke[13], suggesting that 160 patients per million population might benefit from CEA. Other authors interpret the epidemiological data differently and suggest that this figure might be reduced by half[4] or one-third[11]. Any figure may be an underestimate as over 50 per cent of TIAs are not reported to general practitioners[7,14].

Paper accepted 22 April 1996

Methods and results

The number of CEAs performed in the years 1990–1993 and population data for the English health regions were supplied by the Department of Health from Hospital Episode Statistics. Similar data for the health boards of Scotland from 1990–1993 were supplied by the Information and Statistics Division of the National Health Service in Scotland. Northern Irish data for 1989–1994 were supplied by the Strategy and Intelligence Group of the Department of Health and Social Services.

England

The rates of CEA per million population for the 3 years from April 1990 to April 1993 are shown in *Table 1*. The number of CEAs increased over time. There are variations in the rates between health regions; for instance South West Thames had a rate of 11·5 CEAs per million population in 1992–1993 while Yorkshire had a rate of 67·5 CEAs per million population. The latter rate represents one-third of the number that might be predicted for its population base and one-sixth of those that might have been expected to be carried out in an equivalent setting in the USA.

Table 1 Annual numbers and rates of carotid endarterectomy in England, Scotland and Northern Ireland compared with predicted rates (from epidemiological data) and equivalent rates in the USA

Area	Years*					Predicted annual CEA rate	CEAs at USA rate
	1989–1990	1990–1991†	1991–1992‡	1992–1993§	1993–1994¶		
England (population 45 million)							
No of operations		584	1288	1563		7200	16 200
CEAs per million		13·0	28·6	34·7			
Scotland (population 5·1 million)							
No. of operations		72	143	285	323	820	1 850
CEAs per million		14·1	28·0	55·9	63·3		
Northern Ireland (population 2·1 million)							
No. of operations	57	30	41	14	57	335	760
CEAs per million	27·1	14·3	19·5	6·7	27·1		

For England, number of operations relates to 'estimated number of Finished Consultant Episodes' for OPCS4 (Office of Population Census and Surveys) codes L29.4 and 5, and L29.8 and 9 combined (Department of Health; latest available estimate 1995). The number of operations performed in Scotland is derived from 'discharges' rather than Finished Consultant Episodes for the same OPCS codes as England *English and Northern Irish data are for financial years; Scottish data are given for calendar years †1990, ‡1991, §1992 and ¶1993 CEA, carotid endarterectomy

Scotland

Table 1 illustrates the CEA rates for Scotland. The Scottish Health Boards also show wide variation in the rate of CEA with an increase over time. Three health boards, Ayrshire and Arran, Dumfries and Galloway, and Tayside had CEA rates of greater than 100 per million population in 1993; Tayside had a rate of 134·1 in that year. The average Scottish CEA rate was 63·4 per million in 1993.

Northern Ireland

CEA rates are shown in *Table 1*. The years 1989–1994 are financial years. The 'coverage of diagnosis figure' – an estimate of data completeness – for 1992–1993 is only 75 per cent which might explain the strikingly low rate of 14 CEAs per million in this year. The data for 1993–1994 are incomplete with 1 per cent of all data unavailable. These anomalies make comment on this information speculative.

Discussion

Reduction in the number of stroke victims would have marked implications on health care budgeting but to attempt to do this by using CEA would have a great effect on the provision of surgical services. The most recent figures (*Table 1*) show that the English CEA rate is less than 40 CEAs per million. This probably represents only one-third of the workload needed to provide the greatest impact on stroke and only one-sixth of that carried out in the USA.

While financial constraints in the National Health Service and financial incentives in the USA may affect CEA rates, TIA and stroke rates are remarkably similar in these countries[5]. It is unclear whether patients in the UK with carotid artery disease are not diagnosed, not investigated, not referred or simply not operated on. It may be that the results of the ECST and NASCET are not widely known by general practitioners[3], which would affect patient referral. Conversely, the yearly doubling of the Scottish CEA rate between 1990 and 1992 may reflect the impact of these studies on general practitioners.

The effect of the type of healthcare provision may be crucial. The Australian CEA rate for the public hospital system in 1993 and 1994 was 210 per million population (M. Appleberg, personal communication), while the Swedish rate in 1994 was 58 per million population[15].

Data reliability is important. The accuracy of the Scottish morbidity data for abdominal aortic aneurysm has recently been called into question[16]. The incomplete Northern Irish data detected by 'coverage of diagnosis' analysis has been described. The Department of Health figures for England are 'grossed' to compensate for missing data; valid diagnostic coverage is greater than 80 per cent. The Information and Statistics Division of the National Health Service in Scotland reports no data deficiencies.

If attitudes change in the UK, market forces may require an increased provision of surgical intervention. This should be welcomed, but the potential scale of the demand is worrying. To perform an equivalent of half of the CEAs currently carried out in the USA, each British surgeon would need to perform between five and six times more CEAs than at present.

Vein morphology and bypass graft stenosis

K. VARTY, K. PORTER, P. R. F. BELL and N. J. M. LONDON

Department of Surgery, University of Leicester, Clinical Sciences Building, Leicester Royal Infirmary, Leicester LE2 7LX, UK
Correspondence to: Mr K. Varty

Vein wall morphology (intimal and medial thickness) was studied in a consecutive series of 100 veins before organ culture. The development of a proliferative neointima after 14 days in culture was quantified by measuring neointimal thickness, and the relationship between this and the original vein wall morphology was investigated. The correlation between the intimal or medial thickness before culture and neointimal thickness following culture was poor (r_S intima/neointima = 0·21, r_S media/neointima = 0·09). Long saphenous vein biopsies were obtained from 53 patients at the time of infrainguinal bypass surgery and their morphology was studied as above. Median intimal and medial thickness before grafting was 21 (range 2–208) and 245 (range 108–557) μm respectively. After 12 months in a colour duplex graft surveillance programme, 46 grafts were patent and 17 of these had developed a stenosis. There was no difference in intimal (28 *versus* 19 μm, $P = 0·1$) or medial (247 *versus* 245 μm, $P = 0·47$) thickness between stenosed and non-stenosed grafts respectively. Both the laboratory and clinical evidence from this study fail to support the hypothesis that pre-existing vein wall thickening is a key factor in the aetiology of vein graft stenosis.

Vein remains the conduit of choice for lower-limb arterial bypass grafts, the ipsilateral long saphenous vein being the usual and most convenient source. However, in many patients undergoing coronary and peripheral artery bypass the long saphenous vein has been shown to be abnormal or diseased on microscopic examination[1–5]. Panetta and colleagues[6] have demonstrated at the macroscopic level that palpably thickened, varicosed, calcified or recanalized veins have a poor patency rate compared with 'normal' veins (30-month patency 32 *versus* 73 per cent). These findings are not perhaps surprising and it is now widely accepted that vein that is of 'poor quality' on gross inspection at the time of surgery should probably be excised and replaced with vein from an alternative source. Further evidence has emerged, however, suggesting that even microscopic changes in wall morphology may influence graft performance[7,8]. This has potentially greater implications for surgical practice since the detection of these more subtle changes in the vein at the time of grafting is difficult and largely beyond current surgical technique or technology[9]. These veins appear to be perfectly normal on physical inspection and eminently suitable for use as a graft[7]. Before adopting techniques such as intraoperative vein biopsy[7], vein wall compliance measurement[8] or intravascular ultrasonography[10] in an attempt to detect this subclinical vein wall thickening, further evaluation of the importance of this variable on clinical graft outcome seems warranted. The aim of this study, therefore, was to analyse the correlation between long saphenous vein morphology and the process of intimal hyperplasia leading to graft stenosis.

Patients and methods

Histological analysis

The techniques used to collect, transport and process samples of long saphenous vein for histological analysis have been described previously[11]. In brief, minimal handling of the vein occurred during surgery, and the vein biopsy was taken before preparation for grafting and placed immediately in calcium-free Krebs–Ringer solution to counteract spasm. Fixation was always performed under tension by opening the vein longitudinally and pinning it on to a resin gel base with the luminal surface uppermost. During this process the vein wall can be stretched out to maximum length at which point there is strong resistance to further stretch. The reproducibility of this technique has been validated previously[11]. Formal saline (10 per cent) was used for overnight fixation followed by embedding in paraffin wax. Transverse sections of the vein were stained with Millers elastin and monoclonal smooth muscle actin. All measurements were performed by two independent observers taking the mean of 30 values per section using a computerized image analysis system (Improvision, Canley, UK). All vein sections were coded so that the observers did not know from which patient the section had originated, thereby preventing any bias.

In vitro *intimal hyperplasia*

During organ culture, the long saphenous vein develops a cellular neointima with several of the features of intimal hyperplasia seen in retrieved stenosed vein grafts[12]. This *in vitro* model of intimal hyperplasia has been established in the authors' laboratories[13]. For each vein put into culture a control segment of uncultured vein is fixed under tension to provide a histological baseline. To study the influence of pre-existing vein wall histological abnormalities on the development of intimal hyperplasia in culture, intimal and medial thicknesses were measured in a consecutive series of 100 veins before culture, and correlated with neointimal thickness after 14 days. The intima was defined as the layer of vein wall between the endothelium and the internal elastic lamina, the media as the layer between the internal elastic lamina and the adventitia, and the neointima as the cellular layer developing in culture beneath the endothelium but superficial to the original intima. All veins were retrieved from patients undergoing arterial surgery for either coronary or peripheral bypass grafting or carotid endarterectomy where vein was used as a patch.

Clinical graft stenosis

In this prospective study, samples of long saphenous vein were taken from 53 patients undergoing lower-limb vein bypass grafts and analysed as above. The biopsy was always taken from the distal long saphenous vein just beyond the segment used for the actual graft. Previous studies[8] and the authors' own observations have suggested an increased incidence of intimal changes in the distal long saphenous vein. When a section of 'poor-quality' vein was excised during surgery, this was not used for histology since

Paper accepted 29 May 1996

it was unlikely to be representative of the remainder of the graft. Some mildly varicosed veins were used as grafts during the period of the research, but these were not included in the study. The aim was to restrict this enquiry to veins that were judged at the time of surgery by visual inspection and palpation to be normal and suitable for the purpose of bypass grafting.

Three patients had grafts that failed within 30 days and were excluded from the study. The remaining 50 patients (37 men and 13 women of median age 71 years) entered a colour duplex graft surveillance programme for the detection of graft stenosis[14]. Three grafts failed and one patient died in the first 3 months, leaving 46 grafts which completed follow-up to a minimum of 12 (median 12, range 12–31) months. Two of the failed grafts occurred in diabetic patients with limited run-off but the cause of failure in the third graft was unknown. There were 28 femorocrural, 16 femoropopliteal below-knee and two femoropopliteal above-knee grafts; all were inserted for critical limb ischaemia apart from two for claudication and three for popliteal aneurysm. Six of the grafts were composite, a section of 'poor-quality' long saphenous vein being excised and replaced with arm vein. At the completion of the study the relationship between the histological features before insertion of the graft and the incidence of graft stenosis was analysed.

Statistical analysis

The correlation between vein wall thickness and neointimal thickness in culture was analysed using Spearman's rank correlation (r_S). The association between graft stenosis and vein wall thickness was analysed with the Mann–Whitney *U* test.

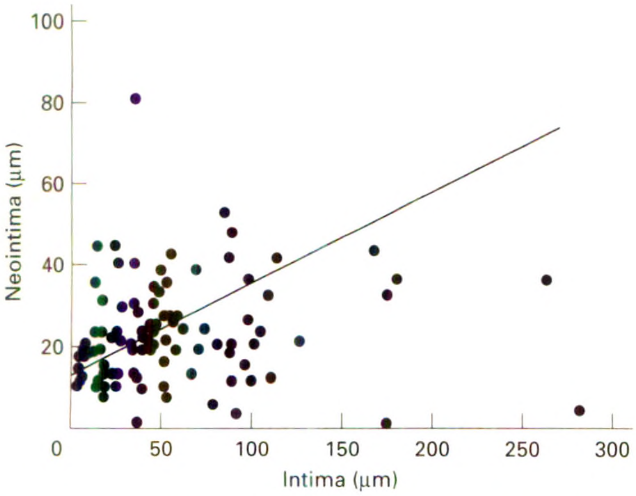

Fig. 1 Scatterplot of intimal thickness in the vein before culture and neointimal thickness after 14 days in culture. ($r_S = 0{\cdot}21$)

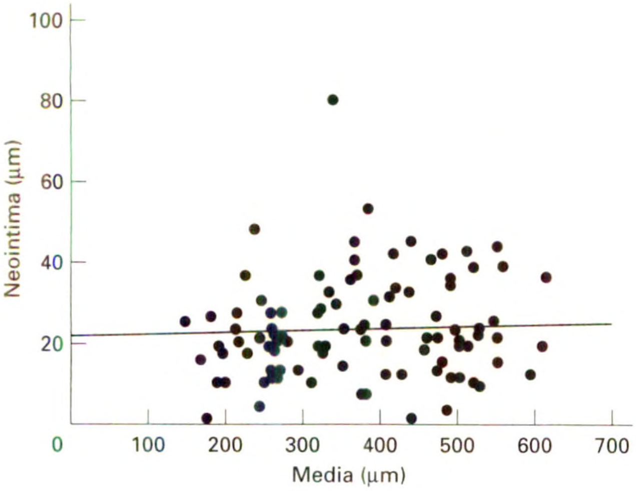

Fig. 2 Scatterplot of medial thickness in the vein before culture and neointimal thickness after 14 days in culture. ($r_S = 0{\cdot}09$)

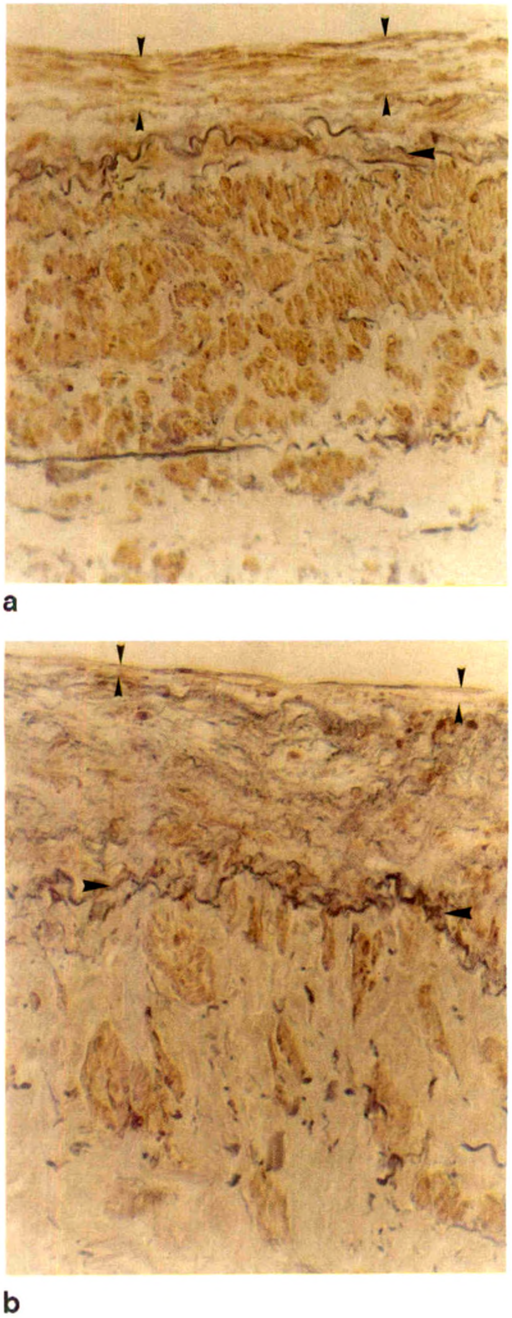

Fig. 3 Transverse sections of vein. **a** Internal elastic lamina (large arrowhead) separating thin intima (12 µm) from media. A neointima (between small arrowheads) consisting of several layers of actin-positive cells has developed in culture, with a thickness of 25 µm. **b** Internal elastic lamina (large arrowhead) delineating a thickened intima (74 µm). Above this a thin neointima (small arrowheads) has formed in culture, less than 10 µm thick. (Smooth muscle actin and Miller's elastin stain, original magnification ×160)

Results

In vitro *intimal hyperplasia*

There was no demonstrable correlation between intimal or medial thickness and the development of neointimal hyperplasia in culture: r_S intima/neointima = 0·21; r_S media/neointima = 0·09 (*Figs. 1* and *2*). No correlation was found between intimal and medial thickness ($r_S = 0·1$) in these veins and the combination of intima plus media also failed to show any relationship to neointimal thickness ($r_S = 0·14$). There were, therefore, a number of veins with no major histological abnormalities before culture which developed a thick neointima in culture (*Fig. 3a*) and a number of veins that were clearly abnormal before culture but which failed to develop a significant neointima in culture (*Fig. 3b*). While this diversity between veins in their propensity to develop neointimal hyperplasia in culture is interesting, it does not appear to be due to pre-existing histological changes in the vein wall.

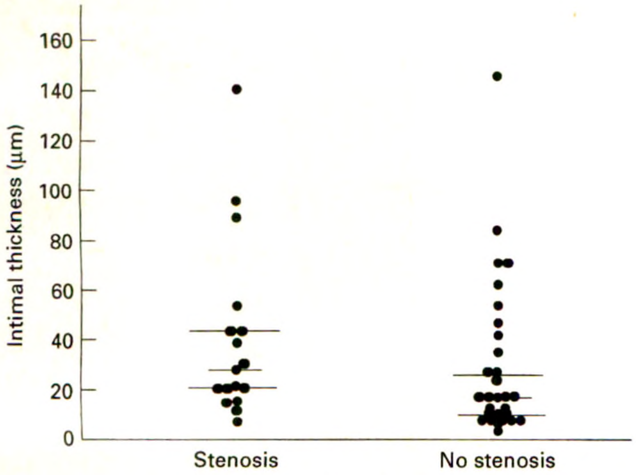

Fig. 4 Comparison of intimal thickness between grafts that did and did not stenose. Wide and narrower bars represent median and 95 per cent confidence interval (c.i.) respectively. There was no difference in intimal thickness between stenosed (median 28 µm) and non-stenosed (19 µm) grafts (95 per cent c.i. − 1·5–22; $P = 0·1$, Mann–Whitney *U* test)

Clinical graft stenosis

Seventeen of 46 grafts developed a stenosis, 13 in the graft body and four at the distal graft anastomosis. Two of the six composite grafts developed borderline stenosis at the venovenostomy which were not treated but closely monitored. These lesions were not included in the data as true graft stenoses. No other lesions developed in the composite grafts. Median time for the detection of a stenosis was 6 (range 2–17) months. Median intimal thickness of the vein before grafting was 21 (range 2–208) µm. The corresponding figure for medial thickness was 245 (range 108–557) µm. There was no difference in intimal thickness between vein grafts that subsequently developed stenosis and those that did not (median 28 *versus* 19 µm, 95 per cent confidence interval (c.i.) −1·5–22, $P = 0·1$) (*Fig. 4*). There were grafts that

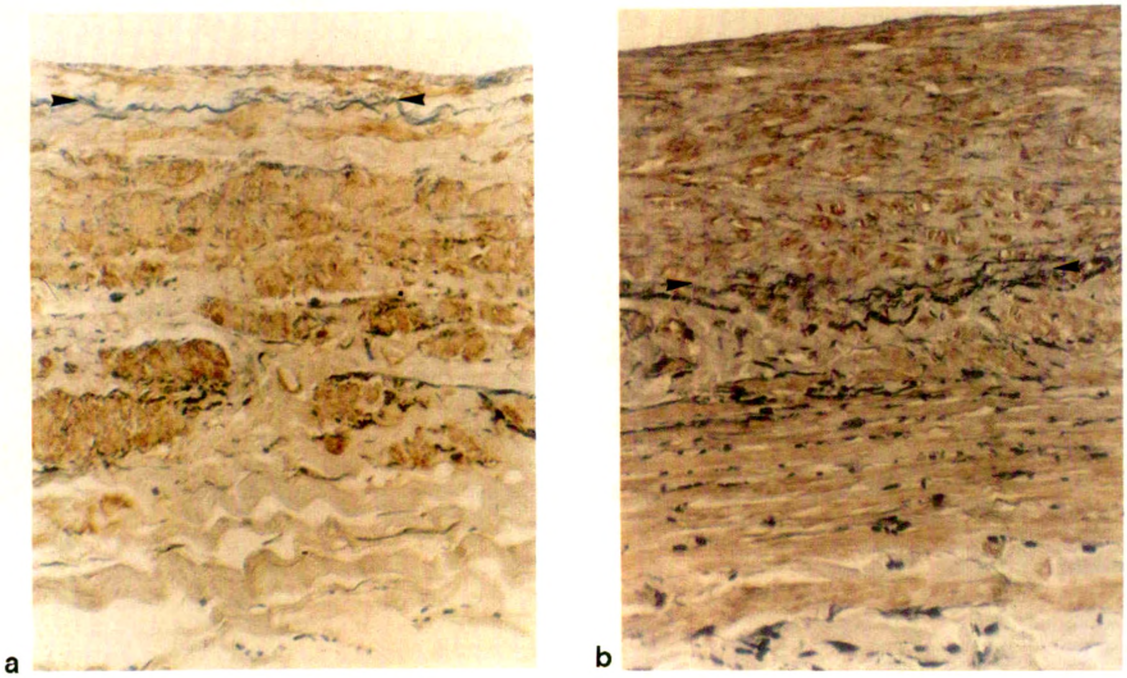

Fig. 5 Transverse sections of vein. **a** Internal elastic lamina (between arrowheads) separating thin intima (11 µm) from medial muscle bundles and adventitia (bottom of figure). This relatively normal long saphenous vein developed a graft stenosis. **b** Internal elastic lamina (between arrowheads) separating thickened intima (95 µm) from circular medial smooth muscle layer (108 µm). Despite this pre-existing abnormality the vein performed well as a graft without stenosis. (Smooth muscle actin and Miller's elastin stain, original magnification × 160)

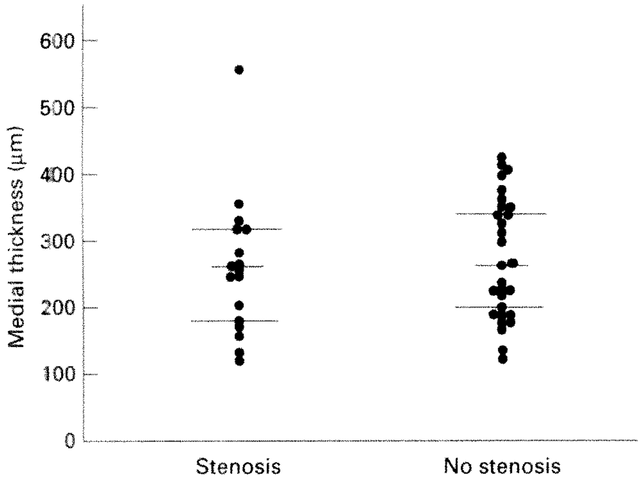

Fig. 6 Comparison of medial thickness between grafts that did and did not stenose. Wide and narrower bars indicate median and 95 per cent confidence interval (c.i.) respectively. There was no difference in medial thickness between stenosed (median 247 μm) and non-stenosed (245 μm) grafts (95 per cent c.i. −62–40; $P = 0{\cdot}47$, Mann–Whitney *U* test)

originally had no major histological abnormalities which went on to stenose (*Fig. 5a*) and, conversely, grafts with marked intimal thickening in the original vein which did not stenose (*Fig. 5b*). Similarly, there were no significant differences in medial dimensions between grafts that stenosed and those that did not (median 247 *versus* 245 μm, 95 per cent c.i. −62–40, $P = 0{\cdot}47$) (*Fig. 6*). A combined intimal plus medial thickness measurement was computed for each vein but no relationship between this and graft stenosis was apparent ($P = 0{\cdot}64$). Reanalysis of all the data based on true intragraft stenoses alone, excluding the anastomotic lesions, produced similar results.

Three grafts that failed during surveillance were excluded from the study since the precise cause of failure was unknown and no graft stenosis had been shown on duplex scanning. The intimal thickness in these veins was 6, 25 and 139 μm respectively. Inclusion of these figures in the above analysis as grafts that did not stenose again did not alter the statistical result of the study.

Discussion

The wide variation in the morphology of the human long saphenous vein in patients undergoing arterial surgery is confirmed in this study. In particular, veins used for bypass grafting that were selected as macroscopically 'normal' during surgery proved still to be very variable in microscopic structure. Although angioscopy can be used to screen for gross vein abnormalities such as webs, calcification, thrombus and retained valve cusps[9,15], its ability to detect more subtle abnormalities, such as intimal thickening, is limited[9]. It is clear, therefore, that with current surgical techniques many veins with a thickened cellular intima are being used as bypass grafts. The important question is whether this is of detriment to the success of the bypass procedure.

Marin and colleagues[7] studied microscopic abnormalities in vein biopsies taken at the time of surgery and fixed under distension of 100 mmHg. They found that intimomedial thickening and cellularity were strongly associated with failed or failing grafts at 18–30 months. Davies and co-workers[8] have also demonstrated a link between veins of poor compliance, usually due to high-grade intimal hyperplasia, and subsequent graft stenosis. In contrast to these findings, Leu and colleagues[16], studying the morphology of 318 human long saphenous veins, concluded that 'phlebosclerosis' was common in autologous vein grafts and of little consequence for the survival of the graft. Cheanvechai and colleagues[1] also described phlebosclerosis in 27 per cent of long saphenous veins used for coronary artery bypass grafting. At follow-up angiography the patency rates were almost identical for grafts from normal (87·9 per cent) or phlebosclerotic (89·5 per cent) veins. There is, therefore, some disagreement in the published literature regarding the significance of long saphenous vein morphology in relation to graft survival, although the more recent evidence[7,8] has strengthened the argument that there is a link.

The *in vitro* data from the present study reveal no correlation between intimal or medial thickness and the development of a neointima in organ culture. This lends no support to the hypothesis that veins with a thickened intima might have an additional proliferative potential for forming a neointima above that of 'normal' vein with a thin intima. In keeping with this, the clinical study of infrainguinal vein bypass grafts failed to demonstrate any clear association between pre-existing intimal or medial thickening and subsequent graft stenosis. Although a small increase in intimal thickness was noted in the group with stenosis (28 *versus* 19 μm), the limited clinical significance of this is shown in *Fig. 4*. The wide variation in intimal thickness produces a large overlap between the stenotic and non-stenotic groups. In practice, therefore, a single measurement of intimal thickness taken from a vein biopsy at the time of surgery would be a poor predictor of subsequent graft performance. Although in a larger study a statistical rejection of the null hypothesis might possibly emerge (type II error), the lack of clear separation between stenotic and non-stenotic grafts would remain. Vein morphology by present methods, therefore, is unlikely ever to be a clinically useful indicator of the risk of graft stenosis. Although wide, the 95 per cent confidence intervals constructed for the sample of veins in this study support the null hypothesis that there is no difference in intimal thickness between grafts that subsequently stenose and those that do not.

These *in vivo* results differ from those of the previous studies by Marin *et al.*[7] and Davies and colleagues[8]. Part of the explanation for these contrasting findings may lie in the different methods used for assessing vein wall morphology in the three studies. Although Marin *et al.* measured intimal thickness, the actual anatomical landmarks used to define this are unclear. The present authors have found that a specific elastin and smooth muscle stain is often necessary to delineate the internal elastic lamina, which defines the extent of the intima. Using a different staining technique, Marin and colleagues quoted values of 'intimal thickness' approximately tenfold greater than those in the present study; these actually refer to a combined intima plus inner media measurement. A measurement of intima plus media in the present study also failed to predict graft stenosis. Davies and colleagues[8] used a semiquantitative, subjective, grading system to categorize intimal thickening and, again, it is difficult to correlate these grades with the thickness measurements made under tension in the present study. The three studies, although similarly concerned with the link between vein morphology and graft outcome, have used different measurements and so are not directly comparable. A further issue is the focal nature of some of the changes seen in the long saphenous vein. A single biopsy from the vein may miss features present at other levels. This factor could explain the lack of correlation between biopsy features and graft stenosis in the present study, but it makes the good correlation found in the studies of Marin *et al.* and Davies and co-workers surprising.

The other unknown variable between these three studies is the selection of patients for surgery. In particular, the criteria used to define a vein as suitable for grafting rather than use a prosthetic alternative may vary between the studies. The policy in this unit is to favour strongly the use of vein in preference to prosthetic graft whenever possible. It seems unlikely, therefore, that more 'diseased' veins with greater pre-existing abnormalities were used in the other studies[7,8] with consequently different results.

The anatomical intima and media of the vein wall has been measured before grafting; no difference was detected in either of these features between grafts that stenosed and those that did not. Although Marin and co-workers[7] promoted vein biopsy at the time of grafting as a means of identifying 'at risk' grafts, after the experience of 50 infrainguinal vein grafts the authors have now abandoned this practice. The morphology of the long saphenous vein does not appear to play a major role in the aetiology of vein bypass graft stenosis.

Colour duplex ultrasonography in the rational management of chronic venous leg ulcers

A. J. GRABS, M. C. WAKELY, I. NYAMEKYE, A. S. K. GHAURI and K. R. POSKITT

Cheltenham General Hospital, Sandford Road, Cheltenham GL53 7AN, UK
Correspondence to: Mr K. R. Poskitt

Colour duplex ultrasonographic imaging has largely replaced venography in the assessment of lower-limb venous disorders. This is a study of the use of duplex in the management of patients with chronic venous ulceration in community ulcer clinics. Patients with chronic leg ulceration and an ankle : brachial pressure index of 0·85 or greater were studied. Assessment of venous competence in both the deep and superficial systems of the affected and unaffected legs was performed using colour venous duplex imaging. Reflux was defined as reverse flow for greater than 1 s after manual calf compression. One hundred consecutive patients were assessed over 15 months. Of 111 ulcerated legs, 96 had active ulceration, while 15 had been ulcerated within the previous 6 months. Fifty-seven (51 per cent) of the 111 ulcerated legs had superficial incompetence alone (88 per cent long saphenous system or its perforators, 12 per cent short saphenous system). Six legs (5 per cent) had isolated deep venous incompetence. Forty-two legs had mixed superficial and deep venous reflux; 22 of these had undergone previous venous surgery. Colour venous duplex assessment demonstrated superficial venous disease in approximately half of limbs with chronic leg ulceration. Venous dysfunction in these patients is potentially curable by surgery.

Chronic leg ulceration is a relapsing condition with a prevalence of between 1·1 and 1·8 per cent; approximately 1 per cent of the population will develop leg ulceration during their lifetime[1–3]. In the UK there is an ulcer-prone population of about 400 000 patients of whom one-quarter will have active disease at any one time. Throughout the UK venous ulcer treatment accounts for 1·3 per cent of the total health care budget and up to 90 per cent are treated in the community[4]. Over 75 per cent of all leg ulcers have underlying venous pathology which can be treated with elevation and compression bandaging. However, successful treatment is followed by high recurrence rates ranging from 22 to 69 per cent at 1 year[5–7].

Use of central diagnostic and advisory services under the direction of vascular surgeons allows the underlying aetiology to be established. This may improve the overall success of treatment and reduce the burden on health resources[8–10]. Colour duplex ultrasonography is a fast and non-invasive assessment, gives anatomical and functional information, and has largely replaced venography in the assessment of lower-limb venous disorders[11–13]. Primary use of duplex to identify patients with chronic venous ulceration in whom surgery might be of benefit is reported.

Patients and methods

Patients referred to community-based leg ulcer clinics were studied. Patients were included in the study if ulceration was active or had been present within the previous 6 months. A chronic ulcer was defined as being present for at least 1 month. Patients with an ankle : brachial pressure index below 0·85 were excluded from the study. A standard pro forma was used to record clinical details of the ulcer such as a history of previous and present ulcers, previous deep venous thrombosis, varicose vein surgery or hip surgery. Both limbs were examined for venous disease, and the site and size of ulceration recorded. The ulcer site was defined as follows. zone 1, the foot; zone 2, the gaiter area extending from 2·5 cm below the malleoli to the point where the calf muscles become prominent posteriorly; and zone 3, extending above this point to the knee[8]. Ulcers that extended across zones were classified according to the zone with the major component of ulceration.

Colour venous duplex imaging of both legs was performed with a H.P. 1000 (Hewlett Packard, Massachusetts, USA) using a 7·5- or 4·5-MHz probe depending on leg size. Venous imaging assessed patency and competence of both the superficial and deep venous systems and the above- and below-knee perforating veins. Imaging of the common and superficial femoral veins, the saphenofemoral junction and the long saphenous venous system was done with the patient sitting on the edge of a variable height couch with the examined limb resting on a step and the hip slightly flexed and abducted. The presence of venous reflux was defined as reverse flow for greater than 1 s after manual calf compression. Thigh and below-knee perforating veins were assessed by examination of the long saphenous vein at the above-knee level following application of a tourniquet to the upper thigh and at the midcalf level with the tourniquet just below the knee. The saphenopopliteal junction and short saphenous vein were examined with the leg resting on a step, slightly flexed at the knee.

Vein competence at all sites was classified according to the following criteria: type I, superficial venous incompetence (including perforators); type II, deep venous incompetence; and type III, superficial and deep venous incompetence

Results

One hundred consecutive patients with venous ulcers were assessed over 15 months. There were 66 women and 34 men with a mean age of 69 (range 29–95) years. Active ulceration had been present for a mean period of 11 (range 1–240) months. Seven patients had diabetes mellitus and five rheumatoid arthritis. The majority of patients had unlimited mobility (*Table 1*). Eleven patients had bilateral ulcers, giving a total of 111 legs with 'ulcer disease' within the preceding 6 months and 89 contralateral limbs without previous ulceration within the preceding 6 months. The incidence of deep venous thrombosis, hip or knee surgery and varicose vein surgery for ulcerated and non-ulcerated legs is shown in *Table 2*. Ninety-six legs (86 per cent) were ulcerated at the time of

Paper accepted 24 April 1996

duplex assessment while 15 had been ulcerated within the previous 6 months. Forty-three (39 per cent) of the 111 legs had first-time ulcers and 68 (61 per cent) had recurrent ulcer disease. Sixteen legs (14 per cent) had multiple ulcers. Of the non-ulcerated legs, 19 (18 per cent) had suffered one previous episode of ulceration and 15 (14 per cent) had had ulceration on more than one occasion. A total of 106 (95 per cent) of the ulcers occurred in zone 2, and there were two ulcers in zone 1 and three in zone 3.

Duplex findings were as follows (*Table 3*). In legs with ulcers, 57 had type I superficial incompetence in the absence of deep venous incompetence. The long saphenous system or its perforators showed reflux in 88 per cent of limbs, with the short saphenous system accounting for 12 per cent. Eighteen (32 per cent) of these legs with superficial incompetence alone had previously undergone venous surgery; 12 ulcers had recurred in the operated system. Six legs (5 per cent) had deep venous reflux alone (type II). Forty-two limbs (38 per cent) had mixed superficial and deep incompetence (type III). Incompetence of the deep venous system was of the superficial/common femoral vein in two (of 42 legs), femoral and popliteal veins in 20, and the popliteal vein alone in 20. Twenty-two type III legs had undergone previous venous surgery.

Occluded deep system	2 (2)	0 (0)
Normal study	4 (4)	17 (19)

Values in parentheses are percentages

Eleven patients had previous hip or knee surgery. Deep venous abnormalities were found in six legs, five having reflux disease and one occlusive disease. In the six patients who had significant restriction of mobility (grade I–III), only one had a normal venous duplex scan, three had superficial venous dysfunction and two deep venous dysfunction. Of the 15 ulcerated limbs with a suspected or proven deep vein thrombosis, 14 were demonstrated to have deep venous incompetence or occlusion; the popliteal system was abnormal in all 14 limbs.

Discussion

Knowledge of the underlying superficial or deep venous pathology allows logical management of patients with chronic venous ulceration. Although both types respond to elevation and compression, superficial venous disease may be corrected by surgery. Elevation and compression therapy in community leg ulcer clinics run by specialist nurses heals 80 per cent of venous leg ulcers, with 50–75 per cent healing within 12 weeks of commencing therapy[10,14,15]. Recurrent ulceration is common after such conservative management and can be predicted from knowledge of the underlying venous abnormality[11,14,16–18]. Moffatt *et al.*[19] reported a recurrence rate of 26 per cent at 1 year, with others demonstrating recurrence rates of up to 69 per cent at 2 years[7,20]. As poor compliance regarding compression hosiery and elevation is the usual cause of ulcer recurrence, other more permanent methods of treating venous hypertension may influence long-term results.

In this study duplex was the primary investigation of all patients with lower-limb ulceration. Duplex showed superficial venous reflux alone in over 50 per cent of limbs. These patients could be offered superficial venous surgery with the expectation of preventing recurrent ulceration. In this series, 34 per cent of patients with type I superficial disease had undergone previous venous surgery and, of these, two-thirds had recurrence in the operated venous system. Some 38 per cent of ulcerated legs had duplex evidence of both superficial and deep venous incompetence and, of these, half had undergone previous venous surgery which may have been inappropriate.

In this series, 95 per cent of patients with mixed superficial and deep venous incompetence had popliteal vein incompetence. This is in agreement with previous reports suggesting that the popliteal vein is the gatekeeper of the lower limb[11,21]. Fourteen of the 15 ulcerated limbs with proven or suspected deep vein thrombosis showed popliteal vein dysfunction. There is debate, fuelled by the recent development of subfascial endoscopic ligation of perforating veins, whether surgery has a role in these patients[22]. Correction of all sites of deep to superficial incompetence, including perforators, may improve deep venous function although outcome appears to be related to preoperative popliteal vein function[11,23].

Venous disease is often present in the contralateral non-ulcerated leg; indeed, 33 per cent of the contralateral legs had a history of previous ulceration. These results confirm the phlebographic findings of Stacey and colleagues[24], who stressed the importance of assessing the non-ulcerated limb in patients with leg ulcers.

Colour duplex imaging allows fast and non-invasive assessment of venous pathology in patients with leg ulcers. There was a high incidence of superficial venous disease alone in patients referred to these community-based leg ulcer clinics in whom surgery might be expected to be beneficial. Increasing numbers of patients are treated in specialist leg ulcer clinics and improved healing rates can be achieved. Currently, no emphasis has been placed on identifying patients who may benefit from surgical correction of venous incompetence. Colour duplex ultrasonography is the optimal investigation to define the exact pathology in the venous system so that appropriate treatment options can be discussed with the patient.

Surgical workshop

New graft design to inhibit myointimal hyperplasia in small vessel anastomoses

J. A. BRENNAN, M. A. ENZLER,
A. DA SILVA, T. V. HOW* and P. L. HARRIS
*Department of Vascular Surgery, Royal Liverpool University Hospital and *Department of Clinical Engineering, University of Liverpool, Liverpool, UK*
Correspondence to: Mr J. A. Brennan, Department of Vascular Surgery, 8C Link, Royal Liverpool University Hospital, Prescot Street, Liverpool L7 8XP, UK

Femorodistal bypass in patients in whom autologous vein is either absent or unsuitable requires the use of prosthetic materials, of which expanded polytetrafluoroethylene (PTFE) is the most widely used. Acceptable limb salvage can be achieved but the results are poorer than with vein. The majority of graft failures occur in relation to the distal anastomosis; they are due to a combination of technical problems encountered when suturing a rigid large bore graft to a small artery and to the rapid development of myointimal hyperplasia in the early postoperative period which results in narrowing of the outflow tract. To overcome these problems the use of an interposition cuff or patch of vein at the distal anastomosis has been advocated[1,2]. The most widely adopted of these is probably the Miller cuff and there is now evidence from a randomized study of significantly improved graft patency compared with no cuff when the distal anastomosis is below the knee joint[3].

In addition to facilitating construction of the distal anastomosis, the presence of a cuff seems to suppress the development of myointimal hyperplasia. The reason for this is not known but there is now some evidence to suggest that the geometric configuration of the cuff alters blood flow at the distal anastomosis in a predictable and beneficial way. In both bench and *in vivo* studies stable coherent vortices are seen to form during the deceleration phase of the cardiac cycle, persisting into diastole[4]. It is postulated that this non-turbulent flow pattern has the dual effect of maintaining high shear stresses and preventing preferential accumulation of blood products at critical sites within the anastomosis, both of which would reduce the propensity for myointimal hyperplasia. If the geometric configuration is the significant factor it may be that the presence of the vein is not important and that creation of a suitably shaped end to the graft may be all that is required.

Materials and methods

Externally supported 6-mm standard wall PTFE (Impra, Tempe, Arizona, USA) was used. The external spiral stent was removed from the distal 4 cm of the graft and a colonic balloon catheter of diameter 18 mm and length 30 mm (Boston Scientific, St Albans, UK) was inserted. The balloon was then fully inflated with water up to its full size (not exceeding 6 atmospheres) using a pressure-gauge syringe with a screw hub. Preliminary studies confirmed that the PTFE grafts used could safely withstand a threefold increase in diameter without rupture and with minimal (less than 5 per cent) recoil. The Miller cuff configuration was then created by cutting across the inflated segment at an angle of 45°, starting at the point of maximum diameter (*Fig. 1*). The final shape was created by minimal trimming. The graft was then resterilized with ethylene oxide gas.

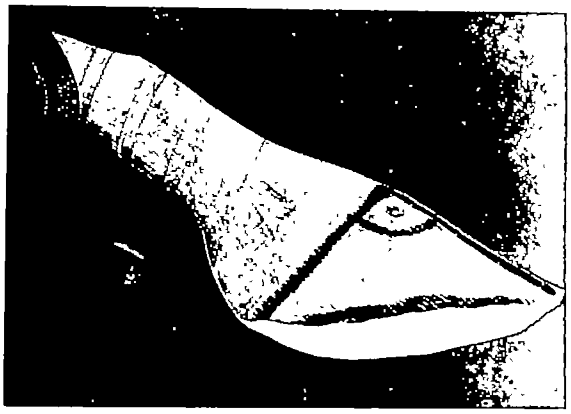

Fig. 1 End of the graft after balloon dilatation and shaping

Clinical studies

Grafts prepared in this fashion have now been used in a small number of patients in whom there was no available autologous vein and the distal anastomosis was below the knee joint. The dilated graft segment has proved easier to handle than the normal graft, with less tendency to turn in, thus facilitating construction of the distal anastomosis. Formal assessment of these grafts is at an early stage but all remain patent and preliminary studies have suggested that similar flow patterns to those seen in both the bench model and the *in vivo* studies of the standard Miller cuff are observed in the precuffed grafts.

Discussion

There is increasing evidence to support the use of an interposition vein cuff at the distal anastomosis between a synthetic graft and a small artery. Much of the impetus for use of a piece of vein stemmed from the belief that it buffered the compliance mismatch between a rigid graft and a smaller, softer artery. There is, however, no scientific evidence to support this hypothesis and other theories must be considered. Preliminary work looking at flow changes at cuffed anastomoses raises the possibility that it may be the anatomical configuration of the cuff rather than the nature of its constituent parts which confers the benefit. Further studies are required before these matters can be resolved and close follow-up of implanted grafts is vital. The early results, however, have encouraged the authors to continue with this line of research.

Short note

Exclusion from day surgery: a 1-year clinical audit

S. K. CLARK, J. P. GRIEVE and
P. E. M. JARRETT
Department of Surgery, Kingston Hospital National Health Service Trust, Kingston upon Thames, UK
Correspondence to Miss S. K Clark, Imperial Cancer Research Fund Colorectal Cancer Unit, St Mark's Hospital, Northwick Park, Harrow HA1 3UJ, UK

Introduction of day surgery increases the efficiency of provision of surgical services. It is endorsed by the Royal College of Surgeons of England[1], and the Audit Commission[2] which has also identified obstacles to its fuller use, including lack of information to assess performance, estimate potential and monitor change[2]. National[2,3] and local audits address issues such as outcome, admission rates and use of facilities. The problem of patients admitted for inpatient surgery who would be suitable for day surgery has not been raised, and these patients are not detected by day unit-based audit. A 1-year prospective study was undertaken of patients added to waiting lists for inguinal hernia repair or ligation and stripping of varicose veins to examine the reasons for rejecting day surgery.

Patients and methods

A record was made of every patient with inguinal hernia or varicose veins when operation was planned. When anyone was added to the inpatient waiting list, reasons why they were considered unsuitable for day surgery were noted by the booking clinician. At the end of the study these indications for admission were reviewed, alongside patients' notes, by the consultant surgeons responsible for the day unit, who assessed whether they were bona fide or whether the patient would actually have been suitable for day surgery.

Results

Some 277 patients were booked for inguinal hernia repair, 160 (58 per cent) as day cases, and 346 patients for varicose vein surgery, 271 (78 per cent) as day cases. The reasons for exclusion from day surgery and their validity are detailed in *Table 1*. Had all been booked appropriately, 63 per cent of inguinal hernia repairs and 88 per cent of varicose vein surgery would have been planned as day cases.

Discussion

Selection criteria similar to those used elsewhere[1,4,5] have been agreed between surgeons and anaesthetists locally and are available in the outpatient department. Restrictions on day surgery because of social circumstances have been largely overcome by having a hospital hotel where patients may stay.

Paper accepted 19 April 1996

Most of the patients booked incorrectly as inpatients had been seen by junior staff new to the hospital. It is likely that they were unclear of differences in selection criteria between hospitals and were unaware of the hotel facilities. Clerical error was the only other repeated cause of misbooking.

The authors intend to avoid unnecessary inpatient admissions by documenting procedures considered suitable for day surgery locally and bringing these, the anaesthetic guidelines and details of the hotel to the attention of new staff before arrival and incorporating them into a redesigned booking form. Matters might be improved further by monitoring the inpatient waiting list, so that every case booked for an operation usually performed in the day unit is brought to the attention of the appropriate consultant.

In a unit performing well beyond the targets suggested by the Audit Commission[2], clinical audit has revealed room for improvement that can be implemented by the adoption of a few simple measures. Continued audit of inpatient admissions alongside day unit activity will identify whether these measures have been effective.

A 4-year prospective audit of the cause of death after infrarenal aortic aneurysm surgery

Correspondence to: Mr P R. Taylor, Department of Surgery, 2nd Floor New Guy's House, Guy's Hospital, St Thomas Street, London SE1 9RT, UK

This study was a 4-year prospective audit of abdominal aortic aneurysm surgery including 222 aneurysm repairs: 106 elective, 76 urgent and 40 emergency. Twenty-five patients died: four who underwent elective surgery, seven urgent and 14 emergency. The two major causes of death, multiple organ failure and colonic ischaemia, were responsible for 11 of the 25 deaths. The three deaths from myocardial infarction all occurred in patients with a leaking aneurysm. Blood loss was significantly higher in patients with multiple organ failure and in those with colonic ischaemia. Methods to identify patients at high risk of massive blood loss and colonic ischaemia may be a way to reduce mortality.

Over the past 30 years the mortality rate from elective repair of abdominal aortic aneurysms (AAAs) has declined from over 15 per cent[1] to less than 5 per cent[2]. Some authors have suggested that elective mortality rates greater than 5 per cent are 'unacceptable and any surgical unit which consistently fails to achieve this figure should not continue to perform this kind of surgery'[3]. In contrast, reported mortality rates for repair of ruptured AAAs have not declined significantly and a recent audit[4] suggests that there is a wide variation in the mortality rate, from 47 to 70 per cent. The mortality rate from rupture, including deaths in the community, was found to be as high as 94 per cent[5].

This study describes the results of a prospective computerized audit of 222 AAA repairs undertaken over a 4-year period. The main causes of death were analysed to look for ways in which the outcome may be improved.

Patients and methods

All patients who had AAA repair between September 1991 and July 1995 under a single vascular consultant (P.R.T.) were entered into a prospective computerized audit. The details recorded are shown in *Table 1*. These were entered on to a custom-designed vascular database developed from Superbase IV (Software Publishing, Bracknell, UK), a Windows-based PC database program. Demographic details were entered on the patient's admission to hospital, and details of the medical history were taken from the patient's notes at the time of surgery. Operation details were recorded immediately after surgery and subsequent progress was entered at the time of discharge from hospital and at a routine 6-week outpatient review. During this interval the consultant provided an *ad hoc* one in one vascular emergency cover to two hospitals as well as performing all elective vascular surgery at both hospitals. Thus almost all the patients admitted to either of the two hospitals for aneurysm surgery are included.

All patients who presented electively with asymptomatic AAAs with a diameter of 5·5 cm or greater were considered for repair unless they had widespread malignancy or were receiving oxygen therapy at home. Aneurysms measuring between 4·0 and 5·5 cm were entered into the small aneurysm study. No upper age limit was applied for elective surgery; instead an attempt was made to assess physiological rather than chronological age. Patients with symptomatic aneurysms (tenderness, back pain or embolic complications) were offered urgent surgery. Those who reached hospital with a ruptured aneurysm had emergency surgery unless they were over 80 years of age with a blood pressure of less than 80 mmHg, despite initial fluid resuscitation.

Outcome

Some 190 patients were men and 32 women. The median age was 71 (range 49–89) years. None of the elective, 11 of the urgent and six of the emergency cases were tertiary referrals. In the study interval three patients were refused elective surgery on the basis of advanced cardiac, respiratory or renal disease not amenable to improvement by intervention.

The principal operator was the consultant in 35 per cent of cases, the senior registrar in 54 per cent and the registrar in 11 per cent, the latter two under supervision.

Results

A total of 222 aneurysm repairs were performed; 106 (48 per cent) were elective, 76 (34 per cent) were urgent and 40 (18 per cent) were emergency repairs for ruptured aneurysms. The commonest risk factor was smoking (68 per cent), followed by hypertension (35 per cent), renal failure (7 per cent) and diabetes (6 per cent). All patients received prophylactic antibiotics. A tube graft was used in

Paper accepted 7 July 1996

67 per cent of repairs, a bifurcated graft to the iliacs in 29 per cent and a bifurcated graft to the femoral arteries in 4 per cent. The external iliac artery was used in preference to the femoral arteries as an outflow site wherever possible to minimize the incidence of graft infection. The inferior mesenteric artery was not reimplanted. The median length of stay in hospital was 12 (range 7–32) days for elective cases, 12 (range 4–80) days for urgent cases and 12 (range 0–182) days for emergency cases.

Table 2 Causes of death in four patients undergoing elective repair of abdominal aortic aneurysm

Cause of death	No. of patients	Comment
Multiple organ failure, ischaemic right colon	1	Heavy bleeding from lumbar vessels during operation causing large blood loss. Laparotomy on day 7 for sepsis; necrotic right colon resected. Died 2 days later
Pneumonia	1	*Staphylococcus aureus* and *Escherichia coli* cultured from sputum
Cerebrovascular accident	1	Nephrectomy 6 weeks before AAA repair for hypernephroma. Adrenalectomy performed at AAA repair for metastasis. On day 6 following AAA repair had massive stroke which computed tomography showed to be a bleed into cerebral metastasis
Aspiration	1	Uneventful AAA repair. Readmitted on day 27 with small bowel obstruction. Aspirated under anaesthesia during laparotomy. Died the next day

AAA, abdominal aortic aneurysm

Table 3 Causes of death in seven patients undergoing urgent aneurysm repair

Cause of death	No. of patients	Comment
Multiple organ failure	3	Very friable aorta. Resuture of proximal anastomosis. Developed renal, cardiac and respiratory failure. Treatment withdrawn on day 19
		Returned to theatre for bleeding from top anastomosis. Massive blood loss. Became inotrope dependent. Died on day 19
		Died on day 19 after initially developing renal failure
Ischaemic colitis	1	Died after prolonged ventilation
Pulmonary embolus	1	Received prophylactic subcutaneous heparin throughout stay
Paraplegia	1	Also developed renal failure Treatment withdrawn after discussion with family
Respiratory failure	1	Impossible to wean from the ventilator. Subsequent investigation showed carcinoma of the bronchus

Overall 25 patients (11 per cent) died within 30 days of surgery. Four had undergone elective repair, seven urgent repair and 14 emergency repair. The causes of death in the elective, urgent and emergency cases are shown in *Tables 2, 3* and *4* respectively. *Table 5* lists the complications according to category of surgery.

Recorded blood loss was compared between patients with the Mann–Whitney *U* test. There was no significant difference in blood loss between elective and urgent cases, but a highly significant difference between elective and emergency cases ($P < 0{\cdot}0001$) and between urgent and emergency cases ($P = 0{\cdot}0001$) (*Fig. 1*). There was no significant difference in median blood loss between patients who had a postoperative myocardial infarction (1200 (range 100–7000) ml) and those who did not (1200 (range 100–15 000) ml). Patients who had a bifurcated graft lost more blood than those with a tube graft (1700 *versus* 1200 ml, $P = 0{\cdot}04$). Patients who developed colonic

Table 4 Causes of death in 14 patients undergoing emergency aneurysm repair

Cause of death	No. of patients	Comment
Multiple organ failure	4	Hypotensive for 10 min before clamping. Died on day 5
		On warfarin Died on day 4
		Torrential bleeding. Abdomen packed to control. Colon ischaemic on day 3. Died on the same day
		Good initial result then developed renal failure. Re-explored as became septic but nothing found. Died on day 19
Myocardial infarction	3	Myocardial infarct on day 4
		Myocardial infarct on day 8
		Myocardial infarct on closing abdomen Unresponsive to inotropes
Bleeding	3	Died on table. Retroaortic renal vein
		Aorta would not hold sutures. Massive blood loss
		No blood clotting products available
Ischaemic colitis	2	Both left-sided colon
Reperfusion	1	White legs in intensive care unit. Returned to theatre and aortobifemoral graft performed. Developed reperfusion syndrome with renal failure. Autopsy showed large bronchial carcinoma
Cerebrovascular accident	1	Died 8 days after operation

ischaemia lost significantly more blood than those who did not (8000 *versus* 1200 ml, $P = 0{\cdot}002$). Those who developed multiple organ failure lost significantly more blood than those who did not (5000 *versus* 1200 ml, $P < 0{\cdot}001$). Patients who died lost significantly more blood than those who survived (5000 *versus* 1100 ml, $P < 0{\cdot}0001$).

There was no significant difference in duration of operation between elective, urgent and emergency cases, between survivors and non-survivors, and between those who developed multiple organ failure or colonic ischaemia and those who did not.

There were three late complications. One aortoenteric fistula presented 6 months after the initial surgery and was treated by removal of the graft and insertion of bilateral axillofemoral grafts. However, this patient became septic while in hospital and refused further treatment; post-mortem examination showed acute diverticular disease. Two patients developed incisional hernias that did not require surgical repair.

Table 5 Complications in patients undergoing elective, urgent and emergency aneurysm repair

Complication	Elective	Urgent	Emergency
Pneumonia	6	7	6
Re-exploration for bleeding	3	3	0
Myocardial infarction	1	2	2
Distal embolus	1	1	0
Gastrointestinal bleed	1	0	0
Pneumothorax (from central venous line)	1	0	0
Renal failure			
Haemofiltration	0	1	5
Haemodialysis	0	0	1
Spinal cord ischaemia	0	1	0
Deep vein thrombosis	0	0	2
Pulmonary embolus	0	1	0
Bleed from chest (combined CABG and AAA repair)	0	1	0
Small bowel obstruction	0	0	1
Diathermy burn	0	0	1

CABG, coronary artery bypass grafting; AAA, abdominal aortic aneurysm

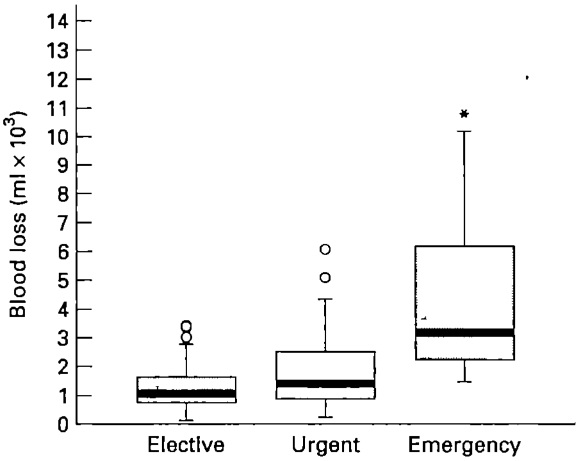

Fig. 1 Boxplot comparing blood loss in elective, urgent and emergency aortic aneurysm repair. Values are: median (dark line), interquartile range (box), full range (whiskers), outliers (O) and extremes (*). $^*P = 0{\cdot}0001$ (emergency *versus* elective and urgent operations, Mann–Whitney *U* test)

Discussion

The mortality rates for elective, urgent and emergency surgery in this series were similar to those in other recent reports[6,7]. Although cardiac complications are considered to be the major cause of morbidity and mortality after aortic aneurysm repair, this was not confirmed in the present series. Myocardial infarction accounted for only three of the 25 deaths and these occurred only in patients undergoing emergency operation. Myocardial infarction comprised 10 per cent of the morbidity in all groups. The diagnosis of myocardial infarction in this series was based on a combination of clinical symptoms or electrocardiographic change associated with a significant rise in the creatinine kinase MB isoenzyme. Because of the high incidence of severe coronary artery disease in patients with aneurysms[8], many recommendations have been made regarding the preoperative cardiac investigations that should be performed in patients undergoing elective aneurysm repair. A recent report[9] showed that there is still a wide variation between hospitals in preoperative cardiac investigation. Patients having elective aneurysm repair routinely had resting electrocardiography and transthoracic echocardiography in this hospital; however, echocardiography detected only four at-risk patients, all of whom could have been recognized by the history and physical examination. Three patients were assessed by coronary angiography, and two were found to have untreatable ischaemic heart disease and were treated conservatively. One patient underwent coronary artery bypass grafting before aortic surgery, and a fourth had unrecognized hypertension that was treated for 3 months, after which he had uneventful aortic surgery. In view of the low rate at which echocardiography actually alters management, the authors have now changed their policy and rely on a detailed history and clinical examination combined with resting electrocardiography only. Patients identified as high risk are referred to a cardiologist for further assessment.

The two major causes of death in this series were multiple organ failure and ischaemic colitis (11 of 25 deaths). This confirms a recently reported series[6] which also found multiple organ failure to be the most important cause of death. The incidence of multiple organ failure was higher in urgent and emergency cases than in elective cases. Multiple organ failure in patients with ruptured AAAs was first described by Tilney *et al.*[10] in 1973 in a series of 18 patients. In the report by Huber *et al.*[6] it was noted that the operating time was significantly longer in non-survivors (7·7 *versus* 5·7 h in survivors) but that there was no significant difference in estimated blood loss between these two groups. However, there was no separate analysis to compare those with and without multiple organ failure. In discussing the results of Huber and co-workers[6], Hollier commented that in his experience 'multiple organ failure after aortic surgery is generally limited to those patients requiring large amounts of blood and crystalloid fluids or those who undergo suprarenal clamping'. The present results confirm the significant association between blood loss and the development of multiple organ failure. It is unclear exactly how these are related. It could be the blood loss itself, the hypotension consequent to the blood loss, or the massive transfusion of homologous blood. Colonic ischaemia, if progressive, may cause multiple organ failure by producing septic shock. It is interesting to note that in this series the development of colonic ischaemia was associated with large blood loss. An explanation for this may be the postoperative use of high concentrations of inotropic drugs, which cause splanchnic vasoconstriction and exacerbate any tendency to colonic ischaemia.

Intestinal ischaemia followed by reperfusion causes acute lung injury in animal models[11], but the mechanism for this is unclear. There is no direct evidence of bacterial translocation[12] but high endotoxin levels have been demonstrated in systemic blood during aortic cross-clamping[13], suggesting that this could, in association with hypotension resulting from massive blood loss, be a trigger for a systemic inflammatory response that may lead to multiple organ failure.

Clearly, massive blood loss is unavoidable in most cases, particularly where an aneurysm has ruptured. The use of autotransfusion may be a more realistic way of reducing the need for transfusion of large quantities of homologous blood in these patients.

Respiratory complications were the commonest cause of morbidity in all categories of patient. Calligaro *et al.*[14] showed in a retrospective review that seven factors were independently associated with the development of major pulmonary complications after aortic surgery. Of these, only poor lung function on respiratory testing may be amenable to improvement before operation. Of note is the fact that infusing large volumes (more than 6 litres) of crystalloid was associated with pulmonary complications.

This prospective audit has shown that the major causes of death after aneurysm repair are multiple organ failure and colonic ischaemia. The previously reported high incidence of cardiac complications has not been confirmed. Both multiple organ failure and colonic ischaemia have been shown to be associated with large perioperative blood loss. Avoidance of large blood loss, whilst clearly desirable, is not always possible. The use of autologous blood transfusion in these circumstances may be beneficial.

Management cost of acute limb ischaemia

B. D. BRAITHWAITE, L. JONES, B. P. HEATHER, P. A. BIRCH and J. J. EARNSHAW

Departments of Surgery and Radiology, Gloucestershire Royal Hospital, Gloucester, UK
Correspondence to Mr B. D. Braithwaite, Queen's Medical Centre, Nottingham NG7 2UH, UK

The cost of attempting limb salvage in patients who presented with acute lower limb ischaemia was recorded prospectively for 20 months. Seventy-five patients were admitted during the study; 45 were treated primarily by radiological intervention and 18 had primary surgery. The remainder were treated conservatively. Patients who had primary surgery required fewer visits to the operating theatre than those who had primary thrombolysis, but there was no difference in the total time that the theatre or radiology suite was occupied: median 2·3 (10th centile range 1·5–5·0) h and 3·0 (2·0–5·0) h respectively. Median (range) cost of disposables for performing surgery was £82 (58-169) and for thrombolysis was £407 (252–596). When the costs of using the theatre or radiology suite were included, the costs of both treatments were similar: surgery £683 (309–1438) and lysis £861 (611–1244). Median (10th centile range) inpatient stay for surgical patients was 9 (3-18) days and for those having thrombolysis 11 (2–29) days. Median (10th centile range) costs for bed occupancy were similar in both groups: surgery £2497 (643–9115) and lysis £2189 (902–6020). Mean cost for attempting limb salvage by surgery was £3429 (1094-10 065) compared with £3230 (1543–8353) for thrombolysis.

The advantage of thrombolysis compared with conventional catheter embolectomy or primary bypass appears to be a reduction in postoperative cardiorespiratory complications associated with surgery[1]. The outcome of thrombolysis, in terms of limb salvage, is comparable to that of surgery, but there is little information on the cost of the two treatments. To address this, the costs of primary thrombolysis and primary surgery in the management of acute arterial occlusion in a district general hospital were recorded prospectively for 20 months, at the same time as a multicentre randomized trial of high-dose bolus administration and low-dose infusion of tissue plasminogen activator (tPA) was in progress[2].

Patients and methods

A protocol for the management of acute limb ischaemia has been used at this hospital for 3 years. Patients who presented with sudden onset of acute arterial occlusion, with an obvious source of embolus and no previous history of peripheral vascular disease, were managed primarily with Fogarty catheter embolectomy and, if necessary, peroperative thrombolysis[3] Patients who did not satisfy the criteria for an embolus were systemically heparinized and then had diagnostic angiography. If there was evidence of neurosensory deficit, angiography was performed urgently; if not, it was carried out the following morning If the angiogram revealed a lesion suitable for intra-arterial thrombolysis patients were randomized either to low-dose infusion or high-dose bolus tPA treatment. All acute vascular admissions were managed by one of two consultant vascular surgeons who had close liaison with consultant radiologists specializing in vascular radiological procedures.

Between September 1993 and April 1995 the cost of treatment for all patients with acute lower limb ischaemia was recorded prospectively. The cost of treatment for primary thrombolysis and primary surgery was calculated using April 1995 prices.

Primary thrombolysis

A record was made of the number of visits to the radiology department and the duration of occupation of the angiography suite. This duration was multiplied by the hourly cost of running the suite (£147) producing a cost per patient for 'radiology time'. This running cost was obtained from the Radiology Directorate Finance Manager and was calculated from the gross annual departmental running costs, including depreciation, divided by the number of patients investigated, to produce a cost per hour (£110). Added to this were the hourly costs of non-medical staff in the suite: senior radiographer (£15), staff nurse (£12) and clerical costs (£10) These costs included routine and 'out-of-hours' workload as the Finance Manager was not able accurately to differentiate between the two. All disposable instruments used during the procedures, including those for secondary angioplasty, were noted, multiplied by the unit cost to the hospital, including value added tax, and added together to give a 'radiology disposables' cost (*Table 1*). Both disposables and radiology time were added to give a 'total radiology cost' If a patient required a secondary surgical procedure then the costs were calculated as for primary surgery (below).

Each patient who received thrombolysis was nursed, whenever possible, in a surgical high-dependency unit (HDU) bed during the tPA infusion and for the first day after catheter removal. If a bed was not available, patients were nursed on a standard 'open' surgical ward by nurses familiar with thrombolytic therapy. The cost for an HDU bed in this hospital was £450 per day or part

Table 1 Inventory and 1995 prices of disposable items used for thrombolysis

Item	Unit cost (£)	Item	Unit cost (£)
Angiogram pack	7·39	Rosen 1·5-mm J guide	18·50
4-Fr straight catheter	8·31	3-mm J guide	5·24

Fresh frozen plasma 500 ml	17·43		

Prices exclude value added tax. CVP, central venous pressure; PTFE, polytetrafluoroethylene

thereof, for a ward bed £300 and, for the one patient who required it, an intensive therapy unit (ITU) bed was £700 per day. These costs included gross running costs of the Surgical Directorate, including non-medical staff. The duration of each patient's stay was multiplied by the cost for an ITU, HDU or ward bed to give a 'bed cost'. If patients required blood products, the cost of these was calculated and recorded as 'blood product cost', the price of blood products was obtained from the Department of Haematology. 'Total radiology cost', 'bed cost', and, where appropriate, 'total surgical cost' and 'blood product cost', were added to give a 'primary thrombolysis cost'. This was divided by the number of limbs salvaged 30 days after treatment to give a figure for the mean cost per limb salvaged.

Primary surgery

For patients who required surgery as a primary treatment, 'bed cost' and 'blood product cost' were calculated as for thrombolysis. 'Surgical time' was calculated by multiplying the time that a patient was present in the operating theatre suite, including time in recovery, by the hourly rate of £250 per hour. This hourly rate was supplied by the Operating Theatre Manager and, in a similar fashion to 'radiology time', was calculated from gross departmental costs, including non-medical staff and depreciation. Surgical disposables were, likewise, recorded for each patient (*Table 2*). If patients required thrombolysis after surgery, radiology costs were calculated as above. Primary surgery and mean surgical costs per limb saved at 30 days were calculated as for thrombolysis.

Data are expressed as median (10th centile range). Presentation of patient details and results are made in two parts: the cost of high-dose bolus therapy was compared with that of low-dose infusion, and analysis of patients' clinical details and financial variables was performed using Mann–Whitney analysis. For categorical data, χ^2 analysis was performed. The combined cost of both techniques of thrombolysis was compared with that of surgery but no statistical analysis was done.

Results

During the study period, 75 patients were admitted with acute lower-limb ischaemia. Forty-four were treated with primary thrombolysis, 18 had primary surgery, one had insertion of an iliac stent and 12 were treated conservatively because of their moribund clinical condition. Only data for those who received thrombolysis or surgery are presented and analysed.

Thrombolysis

There were no significant differences between the clinical features of patients who received high-dose bolus and low-dose infusion of tPA (*Tables 3* and *4*). There were statistically significant differences in treatment details: the high-dose group received higher total doses of tPA ($P=0{\cdot}003$) for a shorter duration ($P=0{\cdot}03$). After thrombolysis, more patients required adjunctive surgical intervention in the high-dose than the low-dose group (five *versus* zero, $P=0{\cdot}01$): In the high-dose group, of the three patients in whom lysis failed, one died from ischaemic bowel within 12 h of lysis, one had an urgent femorofemoral crossover graft and one had an emergency femoropopliteal bypass which thrombosed and was revised to a femorotibial bypass. This last patient also required fasciotomy. One patient with no run-off after lysis proceeded to a successful embolectomy while two other patients required an amputation. The remaining three patients were anticoagulated. The one patient with clinically useful lysis had a vein patch angioplasty and one patient with complete lysis rethrombosed and subsequently had a successful embolectomy. No adjunctive procedures were required in the low-dose group, but one patient with no run-off later had an amputation and a second patient received oral anticoagulant.

Table 3 Demographic details of patients who received thrombolysis with high-dose bolus or low-dose infusion of tissue plasminogen activator

	High-dose bolus tPA ($n=21$)	Low-dose infusion tPA ($n=23$)	P*
Median age (years)	72 (59–81)	74 (53–84)	0·42
Sex ratio (M:F)	13:8	14·9	0·94
Diabetes mellitus	5	6	0·86

Reperfusion injury	1	0	0·30
Death during lysis	1	1	0·95

Values in parentheses are *10th centile range and †percentages. tPA, tissue plasminogen activator. *Mann–Whitney U test

Limb salvage rates and the incidence of major haemorrhage were similar in both groups. One patient in the low-dose group had a retroperitoneal bleed which required operative repair of the catheterized artery. He was transferred to the ITU where he died from a myocardial infarction. Two others needed blood transfusion because of catheter site haemorrhage. In the high-dose group, two patients needed operative repair of the direct graft puncture sites. Two patients died in the high-dose group: one from ischaemic bowel and another from acute limb ischaemia which was not reversed after lysis because of absent run-off. Four patients died in the low-dose group from myocardial infarction (two), pulmonary embolus (one) and general deterioration (one).

Surgery

Eighteen patients were treated with primary surgery. Eleven required femoral embolectomy alone, while four had embolectomy followed by a bypass graft. Two additional patients had emergency bypass procedures and one required a common femoral endarterectomy. Peroperative thrombolysis was carried out in three operations to clear distal run-off vessels seen to be occluded at the time of peroperative angiography. Only one patient had a fasciotomy. One patient required catheter-directed thrombolysis with tPA after rethrombosis following a superficial femoral artery embolectomy 5 days previously.

Complications occurred in eight patients: four of 18, patients had a major haemorrhage, one had a stroke and three went into renal failure after reperfusion of the ischaemic limb. This compares with five of 44 patients with major haemorrhage, no strokes and one reperfusion injury in the group who received thrombolysis. At 30 days, the limb salvage rate was seven of 18, amputation rate two of 18 and mortality rate nine of 18, compared with 35 of 44, three of 44 and six of 44 respectively in the group that received thrombolysis. Death in the surgical group was caused by cardiac arrest (two patients), renal failure (two), mesenteric ischaemia (two), pneumonia (two) and stroke (one).

Cost of thrombolysis

Median number of visits to the radiology suite for patients who received high-dose bolus therapy was 3 (range 2–4), the same as that for low-dose therapy, 3 (range 2–5) ($P = 0{\cdot}15$). Median time for occupying the radiology suite was 3·3 *versus* 3·0 h respectively ($P = 0{\cdot}43$). The cost of radiology disposables was significantly higher in the high-dose group, median (range) £427 (386–592) *versus* £353 (216–616) ($P = 0{\cdot}01$), and therefore the total radiology costs were higher for the high-dose group, £928 (717–1203) *versus* £790 (526–1286) ($P = 0{\cdot}05$). Patients who received high-dose therapy stayed in hospital significantly longer than those in the low-dose group (median 11 *versus* 8 days, $P = 0{\cdot}01$) and therefore incurred significantly higher bed costs (median (range) £2562 (886–8632) *versus* £2043 (862–3288) $P = 0{\cdot}02$) and primary thrombolysis costs, £4055 (1847–11 511) *versus* £2845 (1390–4398), $P = 0{\cdot}01$). Relatively few patients required surgery or blood products so these components were an insignificant part of the primary thrombolysis cost. In terms of cost per limb saved, low-dose thrombolysis was half as expensive as high-dose therapy (mean £6967 *versus* £3535).

Cost of primary surgery and primary thrombolysis

The median number of visits to the operating theatre was smaller in the surgical group than to the radiology department for patients having thrombolysis, 1 (range 1–3) *versus* 3 (1–4), but there was no difference in the total time that the theatre suite was occupied compared with total time in radiology (2·3 *versus* 3·0 h). Median hospital stay was similar in both groups (9 days for surgery *versus* 11 days for thrombolysis). The cost of disposables for performing thrombolysis was higher than that for surgery but the cost for theatre time was greater (*Table 5*).

Table 5 Cost of primary thrombolysis and primary surgery

	£	
	Thrombolysis	Surgery
Cost of radiology and surgical disposables*	407 (252–596)	82 (58–169)
Cost of radiology and surgical time*	441 (293–735)	562 (250–1300)
Total radiology and surgical cost*	861 (611–1244)	683 (309–1438)
Bed cost*	2189 (902–6020)	2497 (643–9115)
Total primary cost*	3230 (1543–8353)	3429 (1094–10 065)
Mean cost per limb salvaged	5124	13 167

*Values are median (10th centile range)

Discussion

These results show that a selective policy for managing acute limb ischaemia with a combination of primary thrombolysis and, where appropriate, primary surgery resulted in a cost to the hospital of approximately £3500 per patient. The study has also shown that high-dose bolus thrombolysis is more expensive but no more time consuming than low-dose therapy

The results may have been influenced by the small numbers involved, the heterogeneous nature of acute limb ischaemia, and the underlying pathology of the disease in each group. The high-dose bolus and low-dose infusion groups were well matched for many clinical features but a greater number required adjunctive surgery in the high-dose group. The need for surgery after thrombolysis and the prolonged hospital stay might reflect more severe disease in the high-dose group. If analysis of the present results is focused on the costs of the primary procedure, not subsequent surgery, then high-dose therapy was only £200 more expensive than low-dose infusion (the extra cost of opening a 50 mg rather than a 20 mg vial of tPA). The time that the radiology suite was occupied did not differ significantly between the groups.

In the second analysis, patients were selected by a protocol for managing acute limb ischaemia. They were not, therefore, comparable to those who required thrombolysis and so statistical analysis is not valid. The high mortality rate in the surgical group was consistent with that in other reports on the association of embolectomy and cardiac related death[4,5]. The early postoperative death of nine patients in the surgical group resulted in low bed occupancy and probably contributed to the low median cost of primary surgery. If this was a randomized study of surgery *versus* thrombolysis, the costs would be different.

The economics of acute limb ischaemia are complex and it is not surprising that there are few publications on the subject. One study in 1988[6] retrospectively reviewed 24 thrombolytic infusions with streptokinase and urokinase for a variety of anatomical lesions. Operating theatre and radiology room charges were similar but the disposable items used for thrombolysis were more expensive than those for surgery. Professional fees were included in the study, which gave the mean total cost per case of thrombolysis as $8232 compared with $8859 for 16 selected surgical procedures for similar lesions. Complete success was defined as successful thrombolysis not requiring surgery and therefore the mean cost at discharge for thrombolysis was four times that of surgery alone. More recently, a retrospective review[7] of 19 native arterial occlusions treated by thrombolysis and 29 treated by surgery noted that initial costs of the two treatments were similar but the mean cost per limb saved after thrombolysis was twice that of surgery ($45 171 *versus* $24 898). The explanation for the increased cost of thrombolysis was the greater number of adjunctive procedures (in 14 of 19 patients) and treatment of complications (in 12 of 19). These two retrospective studies support the results of the present study. The costs of primary surgery and thrombolysis were similar.

The largest comparison of costs of surgery and thrombolysis was presented as part of a randomized trial[1]. Median length of stay after thrombolysis or surgery was 11 days but the median total cost of thrombolysis was greater than that for surgery ($15 672 *versus* $12 253). The costs of the primary procedure were not given. The figures for hospital stay match the results in the present study, but total costs are not comparable because of the different patient groups. At an exchange rate of US $ 1·6 to the £1, the costs of thrombolysis and surgery in the USA are between two and three times higher than those in the UK.

This study has highlighted the difficulty in costing medical treatment[8]. It is one of the first to cost what has been thought of as a labour-intensive form of thrombolysis (high-dose bolus) with the established regimen of low-dose infusion. The study has shown no significant difference in the use or cost of radiological facilities between the methods, except for the cost of more tPA for the high-dose treatment. The major costs of thrombolysis are dependent on the need for surgical intervention for the underlying disease and complications of therapy. For successful and uneventful primary treatment the costs are similar for surgery and thrombolysis.

Still missing the boat with fatal pulmonary embolism

T. E. GILLIES, C. V. RUCKLEY and S. J. NIXON*

Deaths from pulmonary embolism during 1994 among surgical inpatients in three Scottish regions were identified through the Scottish Audit of Surgical Mortality and reviewed to identify the risk factors for thromboembolic disease and the thromboprophylaxis received. Fifty-seven deaths were studied (3 per cent of total deaths); 25 (44 per cent) of the patients had received prophylaxis. Thirty-six patients were in a high-risk group, 19 were at moderate risk and two at low risk. Patients admitted as an emergency, those managed conservatively and those judged to be at moderate risk of thromboembolic disease were most likely not to have received thromboprophylaxis.

Thromboembolic prophylaxis by mechanical or pharmacological methods is effective in reducing the incidence of thromboembolic disease[1,2]. Despite this, the use of prophylaxis is not as widespread as might be wished. The National Confidential Enquiry into Perioperative Deaths highlighted the provision of thromboembolic prophylaxis as an area in which patient management could be improved[3].

The Scottish Audit of Surgical Mortality (SASM) is a national study, which examines every death among surgical inpatients in Scotland, excluding those due to terminal malignancy. This study set out to examine deaths reported to the SASM (excluding the Greater Glasgow regional office) during 1994, in which pulmonary embolism was given as the main cause of death, to assess the level of risk in each case for the development of thromboembolic disease and to identify the type, if any, of prophylaxis used. As the SASM examines deaths only among hospital inpatients, any deaths after discharge will not have been identified.

Patients and methods

A total of 1893 inpatient deaths were reported during 1994, and in 57 (3 per cent) pulmonary embolism was given as the major cause. The case notes were reviewed by a single observer (T.E.G.). Each patient was assigned to a risk group, high, moderate or low, according to the guidelines produced by the Thromboembolic Risk Factors (THRIFT) Consensus Group[2].

Deaths outwith the care of surgeons, non-fatal episodes of thromboembolic disease, deaths due to terminal malignancy and deaths at home following discharge have not been considered. The Aberdeen regional office is the only one to collect information on deaths among patients with orthopaedic trauma routinely.

Statistical analysis was carried out with a χ^2 test using Yates' correction factor for small sample size and Fisher's exact test as appropriate.

Results

Of the 57 patients who died, 18 were inpatients admitted for elective reasons and 39 had been admitted as an emergency. There were 28 women and 29 men of median (range) age 78 (28–93) and 76 (34–88) years respectively. The cause of death was determined by autopsy in 24 patients (42 per cent) and by clinical judgement and investigations in the remainder.

When divided according to the level of risk, 36 patients were at high risk, 19 at moderate risk and two at low risk. Operative intervention was undertaken in 41 patients (72 per cent) with a total of 45 procedures, 14 for malignant disease, 17 for benign disease, and orthopaedic or trauma surgery in 14. Conservative management was followed in 16 patients, seven of whom had malignancy (although none was terminally ill); median stay was 8 (range 1–47) days and 15 had an emergency admission.

A pharmacological, mechanical or a combination thromboprophylaxis regimen was followed in 25 patients (44 per cent). No patient had a contraindication to both mechanical and pharmacological methods of prophylaxis. In all cases pharmacological prophylaxis was commenced during the operative period. The provision of prophylaxis was significantly higher in the high-risk group (22 of 36 patients; corrected $\chi^2 = 8{\cdot}55$, 1 d.f., $P = 0{\cdot}003$) than in patients at moderate risk (three of 19). The use of thromboprophylaxis was lower in patients admitted as an emergency in both the high and moderate risk groups (*Fig. 1*). Only one of the 16 conservatively managed patients received any prophylaxis, although 15 were in the high or moderate risk categories.

There was no statistically significant difference in the use of prophylaxis between the orthopaedic patients and those treated within other specialties.

Paper accepted 2 July 1996

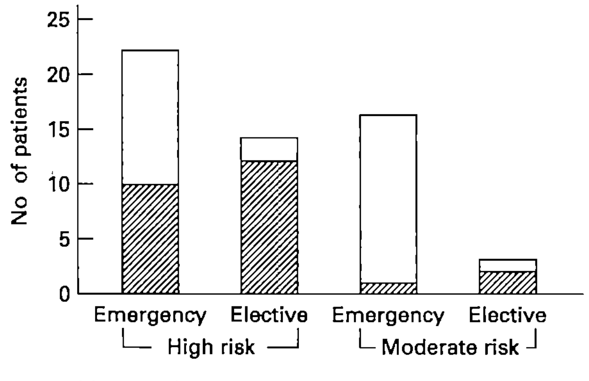

Fig. 1 Antithrombotic prophylaxis by mode of admission. □, No prophylaxis; ▨, received prophylaxis

Discussion

The true incidence of fatal pulmonary embolism is difficult to determine accurately. Without doubt, the number of deaths reported to this study is an underestimate of the perioperative mortality due to pulmonary embolism on account of the low autopsy rate, the nonspecific presentation in many patients and the fact that deaths following discharge were not included. In studies undertaken in countries such as Sweden, where autopsy rates are 75 per cent or more[4], a higher proportion of deaths (10 per cent) has been found to be due to fatal pulmonary embolism. Thromboembolic disease as a contributory or major cause of death will continue to be underdiagnosed in the UK as long as the autopsy rate remains low, and this hampers the development of any prospective study.

The effectiveness of thromboprophylaxis in preventing thromboembolic disease, fatal or otherwise, has been widely addressed. Although effective, it is not absolute in preventing disease, as evidenced by the 44 per cent of patients who died despite receiving prophylaxis.

Mechanical prophylaxis is often overlooked but has been shown to reduce the incidence of venous thromboembolism[5,6] in patients at moderate risk, although no conclusive reduction in the number of fatal pulmonary emboli has been demonstrated. However, stockings must fit accurately and are contraindicated in patients with peripheral arterial disease and/or diabetic neuropathy[7,8]. Intermittent pneumatic compression is a commonly used method, particularly during operation[9]. No mention of it has been made in this study because there was no record of it having been used in any case. It is possible that this was due to poor documentation rather than lack of use. Accurate documentation of the assessment of thromboembolic risk factors and the method of prophylaxis used is important for medicolegal purposes. This is not standard practice at present.

Three groups of patients have been identified from this study as less likely to receive adequate prophylaxis: patients admitted as an emergency, those at moderate risk and those managed without operation. If effective prophylaxis is to be given to all patients at risk, assessment must take place at the time of admission. Delay until the perioperative period omits those managed conservatively and is often overlooked in the emergency case. Better adherence to prophylactic policies would be facilitated by the use of structured clinical record forms into which a section on the assessment of the level of risk could be incorporated. Prophylaxis could then be prescribed according to the unit's preferred policy. A number of collaborative groups have produced guidelines[2,10] that could be used as a basis for local protocols.

Any study of fatal pulmonary embolism will be hampered by difficulties in collecting complete data from the large numbers of patients necessary, and there will remain some patients who die despite prophylaxis. This study has, however, demonstrated that there is still room for improvement in the provision of thromboembolic prophylaxis for surgical inpatients.

Prospective evaluation of dynamic contrast enhanced magnetic resonance imaging in the evaluation of fistula *in ano*

I. J. BECKINGHAM, J. A. SPENCER*, J. WARD*, G. W. DYKE, C. ADAMS and N. S. AMBROSE

*Departments of Surgery and *Radiology, St James's Hospital, Leeds, UK*
Correspondence to: Mr I. J Beckingham, Derby City Hospital, Derby DE22 3NE, UK

Forty-two patients with a suspected diagnosis of fistula *in ano* underwent prospective comparison of digital rectal examination, dynamic contrast enhanced magnetic resonance imaging (DCEMRI) and surgical exploration. There were five discordancies: DCEMRI showed an ischiorectal abscess and track with no enteric connection in one patient who at operation was found to have a well epithelialized primary fistula. Four patients with fistulas on DCEMRI had no enteric opening found at surgery and were treated as having sinuses. Long-term follow-up has shown failure to heal in all patients and further surgery confirmed missed fistula. Compared with final outcome measures DCEMRI had a sensitivity of 97 per cent and specificity of 100 per cent in the detection of fistula. DCEMRI also identified more secondary tracks and was more accurate at identifying complex fistulas than either digital rectal examination alone or surgical exploration.

Fistula *in ano* is a relatively common condition occurring in approximately 1 in 10 000 individuals in the western world[1,2]. The key to the successful management of this condition lies in the correct identification of the fistula in relation to the anatomical structures through which it passes, and to the identification of additional tracks and abscesses which may prevent resolution of the treated primary fistula. While the majority of fistulas are simple and relatively easy to treat[3], those which cross the upper part of the external sphincter or are suprasphincteric or extrasphincteric are difficult to diagnose and pose a risk of incontinence from damage to the anal sphincters during exploration[4]. Missed internal openings or secondary tracks usually result in recurrent fistulas and additional surgery further increases the risk to continence. This prospective study was undertaken to compare the accuracy of digital rectal examination and surgical exploration with dynamic contrast enhanced magnetic resonance imaging (DCEMRI) in the assessment of fistula *in ano*.

Patients and methods

Forty-two consecutive patients referred to this hospital with a prospective diagnosis of fistula *in ano* between January 1994 and July 1995 were studied. There were 36 male patients, and an age range of 26–73 years. Two patients had Crohn's disease and two ulcerative colitis. Nine patients had undergone incision and drainage procedures for perianal or ischiorectal abscesses, and one patient with ulcerative colitis had an ileoanal pouch. Patients were seen initially in outpatient clinics and entered into the study, which involved digital rectal examination followed by magnetic resonance imaging (MRI) and definitive operation. Patients were classified as having no fistula (sinus, abscess, subcutaneous track), simple fistula (single track from skin to bowel) or complex fistula (more than one primary track, secondary tracks, horseshoe extensions or secondary abscesses). Findings were recorded on a standardized operation sheet by surgeons and radiologists (*Fig. 1*); cutaneous and enteric entry sites were noted and primary tracks classified as intersphincteric, trans-sphincteric, suprasphincteric or extrasphincteric according to Parks classification[5]. Neither surgeons nor radiologists were aware of each others' findings before performing their procedures.

- Abscess or collection: Yes/No (indicate site on diagram)
  - Active (i.e. pus present)/quiescent

Fig. 1 Fistula assessment sheet

Magnetic resonance imaging

MRI was performed with the patient in the supine position using a Siemens Magneton 42SP scanner (Siemens, Bracknell, UK). No bowel preparation or special equipment was required. Initial studies showed that the optimal sequences were SE T_2-weighted

Paper accepted 4 June 1996

axial (TE30,60/TR2000) followed by dynamic T_1-weighted TurboFLASH (flat low angle spin) axial and coronal (TE40/TR100/flip angle 80°) before and after enhancement with gadolinium. Gadolinium was administered as an intravenous bolus of 0·1 ml/kg and scans were taken at 10, 30 and 50 s after administration. The total scan took 20 min and was well tolerated by all patients in the study.

Digital assessment

Digital assessment was carried out by a consultant surgeon before surgery and within 7 days of MRI.

Operative findings

Sigmoidoscopy, proctoscopy and gentle probing of the fistula with a blunt-ended probe was performed, followed by surgical exploration by a consultant surgeon. Treatment included laying open of the fistula with removal of lining tissue, drainage of abscesses and fistulectomy. Setons were used in a number of patients. In patients who underwent more than one operation after developing further complications (e.g. failure of healing), information from the second or subsequent operation is included in the final outcome data and not in the initial surgical findings.

Follow-up

All digital and operative procedures were performed without previous knowledge of the MRI findings. Patients were followed until complete healing had occurred, and have been followed for a minimum of 6 months after complete healing. Data assessment sheets of the MRI findings were compared with those of the digital assessment and operative findings and subsequent follow-up.

Results

Primary fistula track

The presence and complexity of fistulas identified by each of the modalities are shown in *Table 1*. The number and type of fistulas according to Parks classification are shown in *Table 2*. DCEMRI identified nine patients without fistula, eight of whom were similarly diagnosed by digital examination and surgical exploration. Five had blind ending or superficial cutaneous tracks (three perianal hydradenitis, one perineal and one pilonidal sinus) and three others were confirmed to have no evidence of a track (one with severe colitis, one linear ulcer, one postanal canal repair). One patient was shown on DCEMRI to have extensive perianal inflammation and an ischiorectal abscess and track but no enteric connection could be seen. Digital examination and surgical exploration revealed a chronic epithelialized connection from the ischiorectal track to the left side of the dentate line. This was the only false-negative MRI result.

Of the 14 simple tracks seen by MRI, 13 were confirmed by digital examination and operation. In one patient shown on MRI to have a low posterior track entering the midline posteriorly, no enteric connection could be demonstrated at operation. This patient has continued to drain pus since operation.

Nineteen fistulas were classified as complex on DCEMRI by virtue of secondary tracks or abscesses. In three patients no enteric connection was identified by digital examination or surgery. In two there was extensive perianal sepsis and in the third patient fibrosis and scarring from previous surgery. All three patients have had continued suppuration despite drainage; two have undergone further surgery which has confirmed the presence of fistula openings at the site shown by DCEMRI. The third patient is awaiting further surgery.

Table 1 Presence and complexity of fistulas

	Digital examination	Surgery	DCEMRI	Final outcome
Simple	21	15	14	14
Complex	8	14	19	20

DCEMRI, dynamic contrast enhanced magnetic resonance imaging

Secondary tracks

Of the 21 fistulas classified as simple by digital examination five were found to be more complex at initial surgery and two more at subsequent procedures. In total DCEMRI identified seven horseshoe tracks, two of which were missed by digital examination, and six ischiorectal tracks, three of which were missed by digital examination. There were three high-level tracks, two suprasphincteric and one extrasphincteric, none of which were predicted by digital examination. One of the suprasphincteric tracks was found at operation but the two other high-level tracks were missed. Their presence was confirmed by continuing discharge and further surgery including laparotomy in the case of the extrasphincteric fistula in a patient with ulcerative colitis.

Discussion

A variety of radiological techniques has been tried to improve preoperative assessment of fistula *in ano* in an attempt to identify patients with complex fistulas and reduce the risk of recurrence. Contrast fistulography[6], endoanal ultrasonography[7] and computed tomography[8], have all been found to be less reliable than digital examination by an experienced surgeon in predicting the course and complexity of fistulas. The St Mark's Hospital study found non-enhanced MRI using STIR (short T_1 recovery time) fat suppression images to be comparable to digital examination and superior to endoanal ultrasonography[9,10]. STIR sequences without enhancement can provide high signals in old healed fibrotic tracks causing misleading interpretations and missed secondary

Table 2 Primary tracks (Parks classification)

	DCEMRI	Surgery	Final outcome
Intersphincteric	24	24‡	24
Trans-sphincteric	6*	4†	7
Suprasphincteric	2	1‡	2
Extrasphincteric	1	0§	1
No fistula	9	13	8

*Dynamic contrast enhanced magnetic resonance imaging (DCEMRI) missed one complex trans-sphincteric fistula; †surgical assessment missed three complex trans-sphincteric fistulas; ‡surgical exploration missed one simple intersphincteric fistula but diagnosed one suprasphincteric fistula as intersphinteric; §extrasphincteric fistula diagnosed surgically as a sinus

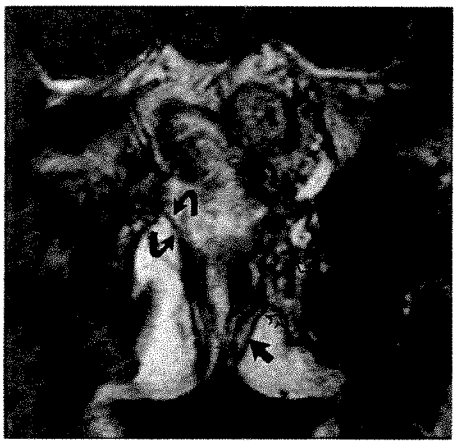

Fig. 2 Coronal plane dynamic contrast enhanced magnetic resonance images of the anal canal showing part of a trans-sphincteric fistula (solid arrow) with a secondary horseshoe abscess (hollow arrows). The pelvic floor is seen clearly on the patient's right side (curved arrows)

Table 3 Sensitivity and specificity of surgery and dynamic contrast enhanced magnetic resonance imaging

	DCEMRI	Surgery
True positive	33	30
False positive	0	0
True negative	8	8
False negative	1	4

Sensitivity and specificity for dynamic contrast enhanced magnetic resonance imaging (DCEMRI) were 97 and 100 per cent respectively, compared with 88 and 100 per cent for surgical exploration

features. In the present study gadolinium contrast was used to produce bright enhancement of active tracks and abscess cavities (*Fig. 2*) which were readily differentiated from the lower signal of old tracks. In addition to making primary tracks easier to identify, five patients had important findings shown only by contrast enhancement (two horseshoe tracks in patients thought to have simple fistulas and three discrete perianal abscesses not resolved from perianal inflammation on unenhanced images). In addition STIR sequences require a longer acquisition time resulting in a doubling of the total scan time.

There was one false-negative result with DCEMRI, which missed a chronic epithelialized track. DCEMRI produces contrast enhancement in granulation tissue which is not present in chronic epithelialized tracks. A similar false-negative result was seen in the St Mark's study[11] using non-enhanced STIR sequencing. However, both of these tracks were easily identified with digital examination alone and did not present diagnostic difficulty in the clinical setting.

The patient population from this unselected study represents a fairly typical group of patients presenting with fistula *in ano*. Studies comparing new techniques for investigation of fistula *in ano* have used surgical exploration as the 'gold standard' investigation with which to compare[7,9,10]. However, it is apparent from all these studies that surgery misses some fistulas since discharge continues after drainage of the 'sinus' or 'simple fistula'. A more accurate assessment of the ability of DCEMRI to predict fistula *in ano* is comparison with the results of surgical findings and the final outcome (including further operations). When this is used DCEMRI had a sensitivity of 97 per cent and specificity of 100 per cent for the correct prediction of a primary fistula track (*Table 3*). MRI was therefore superior to surgical assessment alone (sensitivity 88 per cent, specificity 100 per cent compared with final outcome) which may in part be accounted for by the limitations enforced on the surgeon when severe perianal inflammation may conceal a fistula opening and prevent identification of secondary tracks. Furthermore, the St Mark's studies[9–11], which demonstrated that digital examination was as good as MRI, may not be representative of experience in centres which see fewer complex cases of fistula *in ano*.

This study has shown that DCEMRI is superior to digital examination and surgical assessment in determining the position of the primary fistula track and the complexity of the fistula. Because the predictive value of digital examination to identify simple from complex fistulas in this mixed group of unselected patients was only 50 per cent, it is the authors' current policy to perform preoperative DCEMRI on patients with inflammatory bowel disease, non-healing after treatment of an apparently simple fistula or a recurrent fistula.

Short note

Role of the nurse endoscopist in colorectal practice

V. MOSHAKIS, R. RUBAN and G. WOOD

Colorectal Unit, Department of Surgery, George Eliot Hospital National Health Service Trust, College Street, Nuneaton CV10 7DJ, UK

Correspondence to: Mr V. Moshakis

Recent changes in the provision of colorectal services[1,2] have led the authors to train a nurse endoscopist in colorectal practice[3].

Methods

A registered general nurse was trained in flexible sigmoidoscopy and clinical coloproctology in accordance with an agreed protocol. The training took place during routine endoscopy lists in a medium-sized district general hospital. Under the direct supervision of a consultant (V.M.), the nurse (R.R.) was trained in the three main elements of colorectal endoscopy.

First, theoretical training covered the anatomy, physiology, pathology and clinical aspects of gastrointestinal disease, with special emphasis on the colorectum. Second, general endoscopy equipment training covered the mechanisms, cleaning and maintenance of flexible sigmoidoscopes; the principles and practice of infection control and the function and organization of endoscopy units were also taught. Third, flexible sigmoidoscopy training consisted of observation, performance of supervised procedures and postsigmoidoscopy management in 200 cases.

Fifty procedures were observed, during which continuous teaching of the clinical and technical aspects of endoscopy took place. The trainee then performed 50 supervised procedures. The first 25 were withdrawals and were part of colonoscopy in sedated patients. Following these, 50 flexible sigmoidoscopies were performed, with the trainer immediately available.

The nurse also learnt to use the proctoscope and to inject haemorrhoids, following the practice of the consultant to perform injection at the time of flexible sigmoidoscopy.

Assessment

Both the consultant trainer and pupil were assessed by an independent consultant gastroenterologist (G.W.)

Video recordings were made of 50 trainer and 50 pupil procedures. Data recorded included duration of procedure, depth of insertion, level of colon reached, quality of examination and diagnostic accuracy. The pupil performed 150 solo procedures in her training and assessment. The endoscopist was not identified on the pro forma or video recordings. The assessor scored each criterion and each procedure.

Scores for the pupil and trainer were totalled and compared. The pupil was considered able to perform competent and safe flexible sigmoidoscopy when her scores were equal to or within 15 per cent of those of the trainer.

Results

Total scores did not show any statistically significant difference between trainer and pupil. Quality and accuracy scores were all 94–97 per cent. Trainer and pupil achieved 60 cm insertion in similar numbers of cases (72 and 71 per cent), and reached the descending colon in one-half (50 and 49 per cent) of cases.

Competence in theoretical and endoscopy training was achieved in all areas with 'proficiency' marks awarded in all criteria in the training package.

No complication occurred throughout the training or the assessment.

Discussion

The training protocol was stricter and more thorough than the training of medical personnel recommended by the British Society of Gastroenterology. Assessment by a senior endoscopist not related to the training demonstrated objectively that the pupil had become as good or almost as good a sigmoidoscopist as the trainer. This assessment was based on scores in the main areas of technical skills and diagnostic accuracy.

It is recognized that the assessment is not completely objective. Review of a video recording is not quite representative of the real examination by the endoscope. In addition, the assessor reviewed the examinations without knowledge of the patients' history, so that diagnosis such as haemorrhoids or diverticular disease could be only subjective. Despite its limitations, this attempt objectively to prove the effectiveness of the training is the first such description in gastrointestinal endoscopic training.

A nurse can be taught to practise flexible sigmoidoscopy efficiently and safely. It is concluded that, with expert training and continuing education, the nurse endoscopist can become a vital resource in the colorectal team.

Short note

Disruption of the internal anal sphincter can occur after transanal stapling

R. FAROUK, P. J. DREW, G. S. DUTHIE,
P. W. R. LEE and J. R. T. MONSON
Academic Surgical Unit, University of Hull, Castle Hill Hospital, Cottingham, UK
Correspondence to: Mr R. Farouk, E6A, Section of Colon and Rectal Surgery, Mayo Clinic, 200 First Street SW, Rochester, Minnesota 55 905, USA

Disorders of continence are present in up to 60 per cent of all patients undergoing low anterior resection for rectal cancer[1]. This may be attributed to loss of rectal reservoir[2] with associated impairment of sensory function of the rectum or pelvic floor. Disruption of the anal sphincter complex may also contribute to postoperative continence disorders as a result of division of its innervation and/or anatomical disruption secondary to anal dilatation during transanal anastomosis[3]. Anal sphincter appearances have been studied prospectively by endoanal ultrasonography to determine whether such disruption occurs.

Patients and methods

Thirty-nine patients (18 women; median age 59 years) who underwent anterior resection with a stapled anastomosis for rectal cancer were assessed prospectively before operation, immediately after operation, and 3 months after surgery by endoanal ultrasonography (Bruel and Kjaer, Naerum, Denmark). Preoperative radiotherapy was not given to any of the patients assessed. Twenty-nine patients underwent a double-stapled anastomosis; the others had a purse-string suture inserted transabdominally followed by a transanal stapled anastomosis. The size of the stapling gun used was 29 mm (27 patients), 31 mm (eight) and 28 mm (four).

Results

No internal sphincter defects were observed before operation. External anal sphincter defects were found in three female patients with a previous obstetric history.

Seven patients were observed to have defects of the internal sphincter immediately after stapling; in one a 29-mm stapling gun had been used and in six a 31-mm device. All of these patients had undergone double stapling. These defects were present 3 months after surgery. Three patients had disruption of the entire length of the internal sphincter at one site (*Fig. 1*), three had 50 per cent disruption of the proximal internal sphincter, and one patient had two sites of disruption affecting 50 per cent of the length of the internal sphincter. Five of the seven patients with internal sphincter defects are incontinent of solid stool on more than two occasions per week after a median of 4 (range 3–7) months' follow-up. The remaining two patients still have a defunctioning ileostomy. There were no additional defects in the external sphincter after surgery.

Paper accepted 31 May 1996

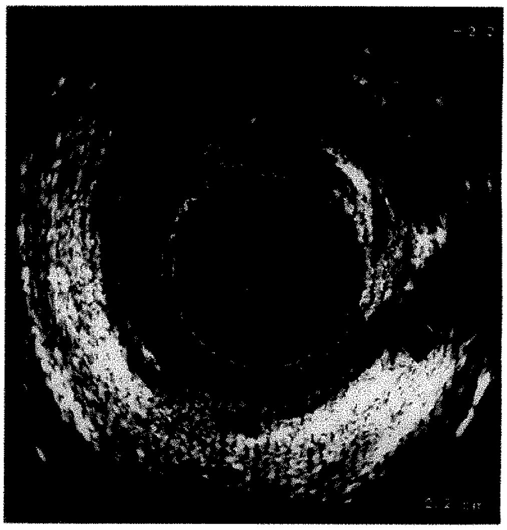

Fig. 1 Endoanal scan revealing complete disruption of the internal sphincter 3 months after low anterior resection completed by a double-stapled anastomosis. The hypoechoic ring of the internal sphincter has been divided and the cut ends of the internal sphincter have retracted (arrows)

Discussion

Up to 43 per cent of patients achieve perfect postoperative continence 5 years after coloanal anastomosis[4]. Of the remaining patients, 34 per cent have 'acceptable' continence with fewer than two episodes of faecal incontinence per week. The remaining patients have more frequent episodes of incontinence requiring daily use of pads[4].

In this study, seven of 39 patients had evidence of internal anal sphincter disruption immediately after a transanal stapling procedure. These defects persisted at 3 months' follow-up. The defects were associated primarily with the use of the larger diameter stapling guns. Similar defects of the internal sphincter have been observed previously by endoanal ultrasonography after ileal pouch–anal anastomosis[5]. Patients with these defects have frequent episodes of faecal incontinence in the early postoperative period.

Disconnection, pouch revision and reconnection of the ileal pouch–anal anastomosis

P. M. SAGAR, R. R. DOZOIS, B. G. WOLFF and K. A. KELLY

Division of Colon and Rectal Surgery, Mayo Clinic and Mayo Foundation, Rochester, Minnesota, USA
Correspondence to: Dr R. R. Dozois, Division of Colon and Rectal Surgery, Mayo Clinic, 200 1st Street SW, Rochester MN 55 905, USA

The aim of this retrospective study was to determine the outcome of patients with a dysfunctional pelvic ileal reservoir in whom disconnection of an ileal pouch–anal anastomosis (IPAA), pouch revision and reanastomosis had been carried out. There were 23 patients (15 women). At the revision operation functional problems were found to be due to a long efferent spout (nine patients), sepsis and/or fistula (four), a redundant blind limb (three), a twisted pouch (three), anastomotic problems (three) or no reservoir (one). The pouch was salvaged in 16 patients and a new pouch was constructed in seven. The pouch–anal anastomosis was resutured in 22 patients and stapled in one. Postoperative complications (all minor) occurred in six patients. Two patients underwent two revisions of IPAA. At a median follow-up of 5 (range 1–10) years, 11 patients reported good to excellent function, five reported fair function and one reported recurrent pouchitis. Revision surgery was unsuccessful in six of 23 patients (three had gross incontinence, two excessive bowel movements and one Crohn's disease), and they subsequently underwent pouch excision. It is concluded that revision of an ileal reservoir and IPAA can be undertaken safely with good results in carefully selected patients.

Ileal pouch–anal anastomosis (IPAA) is well established as the principal elective operation for most patients with chronic ulcerative colitis and familial adenomatous polyposis. As experience has been gained, the procedure has been refined. Since the early descriptions[1], modifications have included the incorporation of an ileal pouch[2], different designs of the pouch[3], reduction in the extent of rectal mucosectomy[4], use of stapling instruments and less manipulation of the anal sphincter. The operation is safe but complex. The incidence of postoperative complications is 30–50 per cent and is related mainly to the experience of the surgical team[4]. The success rate is 95 per cent and the quality of life is usually good[5].

A small subset of patients exists in whom the long-term functional result is poor. Although in many of these cases the problem may be related to recurrent episodes of pouchitis or postoperative pelvic sepsis[6], some patients may benefit from surgical intervention.

The aim of this study was to review patients with an unsatisfactory outcome after IPAA in whom the anastomosis had been taken down, revision surgery had been performed on the pouch and the IPAA reconstructed. The hypothesis was that, in carefully selected patients, such surgical intervention could be achieved safely and with good long-term results.

Patients and methods

Between January 1981 and December 1995 more than 1700 patients underwent IPAA at the Mayo Clinic. Twenty-three patients (15 women) had repeat IPAA with disconnection of the anastomosis, revision of the pouch and repeat IPAA. Most of these patients (19 of 23) had the original anastomosis at other centres. Two patients underwent this repeat procedure twice. The details of the patients are shown in *Table 1*.

An IPAA registry has been maintained to record demographic details, mode of presentation, operative procedure, type of ileal pouch, use of diverting ileostomy and postoperative complications. Preoperative and postoperative data are also recorded and each patient completes a functional questionnaire annually. The questionnaire documents the number of daily and nocturnal bowel movements, daytime and night-time continence with the need to wear a pad, perianal irritation, ability to discriminate flatus from faeces and use of medication.

*Fonkalsrud or lateral ileal reservoir. †This patient had effectively had a J pouch constructed and then placed upstream from the terminal ileum, which was then anastomosed to the anal canal; the terminal ileum thus acted as an efferent spout from the J pouch

Patients who presented with pouch dysfunction underwent standard investigations with inspection and palpation of the IPAA, stool culture, pouchoscopy and multiple biopsies, water-soluble contrast enema, manometry of anal sphincter and pouch, and a small-bowel contrast study if Crohn's disease was suspected.

The notes and registry data of each of the 23 patients were reviewed. As follow-up of all patients on the registry continues prospectively, outcome was determined in every patient. The study was approved by the Mayo Institutional Review Board.

Surgical technique

The patient was placed with the legs elevated in Lloyd-Davies supports. The abdomen was opened and the ileal pouch was

Paper accepted 8 July 1996

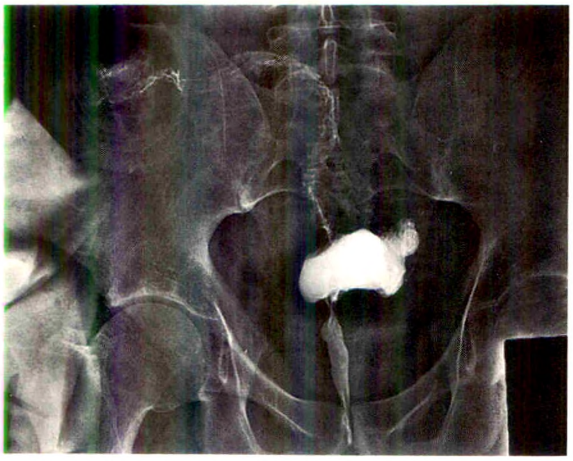

Fig. 1 Water-soluble contrast enema in a patient with a Fonkalsrud (H) pouch. The pouch lies almost transversely in the pelvis and the efferent spout is too long

identified and dissected out with a combination of electrocautery and sharp dissection. When the IPAA had been identified from above, perineal dissection was used to disconnect the anastomosis, and the pouch was delivered out of the abdomen. The pouch was revised according to the nature of the problem. This included excision of a long efferent spout with or without excision of the original pouch (*Fig. 1*), excision of the original pouch with construction of a new pouch, excision of a long blind end (*Fig. 2*), rotation of the pouch on its longitudinal axis and excision of fistulous tracts with repair of the pouch (*Table 2*). The new pouch was then anastomosed to the anal canal. Four anchoring sutures were placed into the walls of the pouch and the levator muscles, and then a series of interrupted absorbable sutures was placed between the pouch and the anal mucosa. The procedure was covered with a diverting ileostomy in all cases. Intestinal continuity was restored 2–3 months later after a water-soluble contrast study had demonstrated satisfactory healing.

Results

Morbidity and mortality

There were no deaths. Postoperative complications developed in six of 23 patients. Five patients developed partial small bowel obstruction, all of which resolved without operation; one patient developed a significant cardiac arrhythmia (junctional rhythm) during operation. The median length of stay in hospital was 10 (range 6–17) days. The ileostomy was closed uneventfully in each patient 8–14 weeks later.

Causes of pouch dysfunction

Nine patients were found to have an excessively long efferent spout (5–11 cm). Four patients had pelvic sepsis and/or fistulas. Three patients had a long mobile blind limb capable of obstructing outflow from the pouch (*Fig. 2*). Three patients were found to have rotated pouches, in one of whom bowel proximal to the pouch had been intussuscepted within the pouch and sutured (presumably accidentally) to the IPAA such that the pouch itself was excluded from the flow of intestinal content. Problems specific to the IPAA included partial separation (one patient), residual disease after a double-stapled anastomosis (one) and a long stenosis (one). Finally, one patient had undergone ileoanal anastomosis with no reservoir.

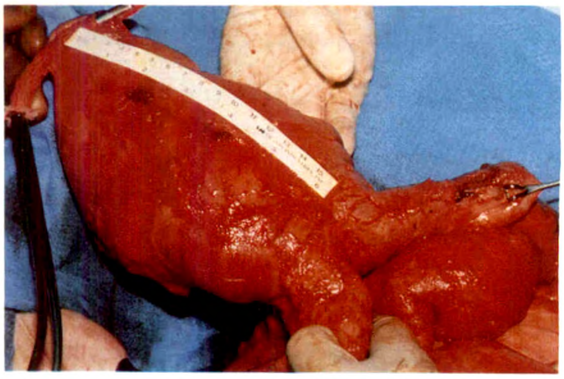

Fig. 2 The blind end of the pouch is long and free to move. As the lower part of this pouch and the blind end filled with stool, the blind limb occluded the upper part of the pouch. Defaecation was difficult and incomplete

Table 2 Indication for reoperation and outcome in 23 patients

Problem	No. of patients	Treatment	Outcome
Long efferent spout	9	New pouch (5) Revised pouch (4)	Success in seven
Sepsis and/or fistula	4	Revised pouch	Success in two
Blind limb	3	Revised pouch	Success in one
Twisted pouch	3	New pouch (1) Old pouch retained (2)	Success in three
IPAA	3	Old pouch retained	Success in three
No pouch	1	New pouch	Success

IPAA, ileal pouch–anal anastomosis

Functional outcome

The eventual outcome of the patients after a median follow-up of 5 (range 1–10) years is shown in *Table 2*. Attempts to salvage the pouch and obtain satisfactory function failed in six of 23 patients. Failure was due to gross faecal incontinence in three patients, excessive frequency of bowel movements in two and unrecognized Crohn's disease in one. The other 17 patients have fair to excellent pouch function with a median frequency of bowel movements of 5 (range 2–11) per 24 h and 1 (range 0–2) at night. Thirteen of the 17 patients are able to discriminate confidently between flatus and faeces such that they are able to pass gas without the need to visit the toilet. Seven patients have perianal irritation, four have occasional faecal seepage (less than once a week) and two need to wear a perianal pad most of the time. Five patients still require antidiarrhoeal medication and two have recurrent episodes of confirmed pouchitis. All these patients are pleased to have opted for repeat IPAA rather than excision of the pouch with permanent ileostomy.

Discussion

As the operation of IPAA has become more widespread, a number of patients have been referred with compli-

Table 3 Complete reconstruction of the ileal pouch–anal anastomosis

Nicholls and Gilbert[10]	1990	6	Long spout	Good function in four patients; two self-catheterize
Fazio and Tjandra[11]	1994	2	Residual disease, dysplasia	Good function in both patients

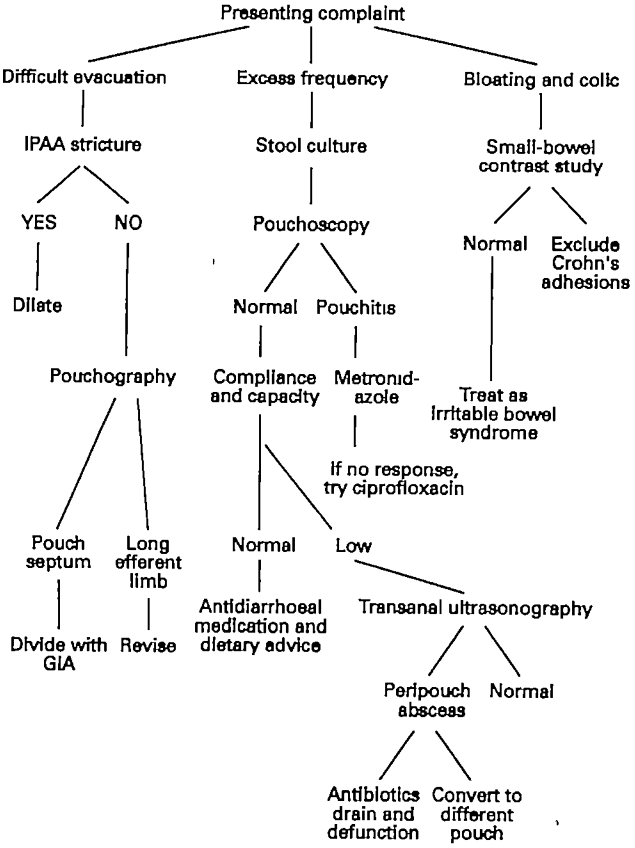

Fig. 3 Investigation of pouch dysfunction. IPAA, ileal pouch–anal anastomosis. GIA (US Surgical, Norwalk, Connecticut, USA)

cations related specifically to the function of the pouch. Many respond to conservative treatment, but some cases are resistant and reoperation may be necessary. Reoperation may involve dilatation of the anastomosis, drainage of perianastomotic abscesses, unroofing of anastomotic sinuses, placement of setons or fistulotomy, or re-establishment of a diverting ileostomy[7]. In a small group of patients, however, these relatively simple procedures are not indicated and disconnection of the IPAA, revision or reconstruction of the pouch and a second IPAA is required (*Table 3*). This study has demonstrated that with careful selection this can be accomplished safely with good functional results in the majority of patients.

Investigation

The selection of patients is crucial. *Fig. 3* shows an algorithm of the investigation of these patients. A water-soluble contrast enema and poor clearance of contrast at the time of defaecating proctography may identify a long efferent spout. The algorithm for patients with excessive frequency of bowel movements is designed to identify non-surgical causes such as infection and pouchitis. Nevertheless, some of these patients may have inadequate evacuation which manifests itself as excessive frequency. A final subset of patients complain of bloating and colic. Although some may have adhesions or Crohn's disease, most seem to have a variant of irritable bowel syndrome and are best referred back to their physician.

Long efferent spout

When the S pouch was first described, a long efferent ileal limb was incorporated in the design to reduce the risk of faecal incontinence[2]. It was later realized that this was both unnecessary and troublesome, because it was associated with incomplete or difficult evacuation, with up to 50 per cent of patients requiring self-catheterization[12]. Although attempts have been made to excise the limb and reanastomose the pouch to the anus by a transanal approach, a transabdominal approach seems to offer the best chance of success[10]. Although the long efferent spout was the main cause of the problem in this subset of nine patients in the present study, coexistent stenosis at the junction between the pouch and spout (which may be acutely angulated) or the spout–anal anastomosis was also apparent to a variable degree. At operation the aim was to excise the spout in its entirety and establish an anastomosis between the most dependent part of the pouch and the anal canal. The original pouch was preserved where possible. The original operative notes often referred to difficulty in obtaining sufficient length to form a tension-free anastomosis. Interestingly, this was never a problem with the repeat operations, presumably because of lengthening of the mesentery in the interim. All patients in the present series were able to evacuate spontaneously after excision of the efferent spout.

Pelvic sepsis and pouch–cutaneous fistula

The rate of pelvic sepsis after IPAA ranges from 0 to 25 per cent[6,13,14]. This rate declines with experience[7] and with use of shorter rectal cuffs[15]. Pelvic sepsis is widely regarded as a major cause of pouch dysfunction. The policy at the Mayo Clinic has been to excise pouches in which the functional result is poor as a consequence of serious pelvic infection. In the present series, pelvic sepsis was the underlying problem in only three patients, two of whom had two attempts at repeating the IPAA. The literature is devoid of any convincing series of successful repeat IPAA after 'true' pelvic sepsis.

One patient had a pouch-cutaneous fistula without sepsis. Complex fistulas that present late suggest hitherto unsuspected Crohn's disease. The presence of a controlled pouch-abdominal wall fistula (without abscess cavity) may warrant revisional IPAA but a stiff, inelastic, ileal pouch that has become fibrotic secondary to sepsis acts as a conduit rather than a reservoir and is best excised.

Separation of the ileal pouch-anal anastomosis

Separation of the IPAA was the reason for repeat IPAA in only one patient. This is, however, not an uncommon postoperative complication and occurs in up to 22 per cent of patients[14,16,17]. It is more common with a hand-sewn than with a stapled anastomosis[18] and is associated with severe gross rectal inflammation with difficult mucosectomy and long rectal cuffs[15]. The majority will either heal spontaneously or respond to operative drainage of associated abscesses, unroofing of anastomotic sinuses or transanal repair of the dehiscence and delayed closure of the ileostomy[7].

Anastomotic stricture

Excessive tension on the IPAA with ischaemia may lead to anastomotic stricture. This is compounded in the presence of perianastomotic sepsis with subsequent fibrosis. A soft stricture is often evident at the time of closure of the ileostomy, which yields to gentle dilatation, and most strictures seen subsequently can be dilated in the surgery. When an anastomotic stricture responds to dilatation, the eventual functional outcome is no different to that of patients without a stricture[19]. A long or tortuous stricture will not respond so easily and repeated attempts at dilatation may aggravate the problem. In such cases, complete revision of the IPAA may be beneficial.

Retained rectal mucosa

Concerns about the possibility of damage to the anal sphincter during transanal mucosectomy led to the development of the double-stapled IPAA in which the anorectum is transected after application of a linear stapler to the top of the anal columns and the use of a circular stapler placed into the anal stump to construct the IPAA. A number of authors have reported a variable length of rectal mucosa left *in situ* as the direct result of this technique. Although only one patient in the present series underwent repeat IPAA because of recurrent symptoms from the residual diseased mucosa, it seems likely that, as the double-stapled technique becomes more popular, more and more patients will require revision surgery because of inadequate eradication of disease at the time of the original operation. Dysplastic change within remnants of rectal mucosa has also been described[11]. Transanal mucosectomy with ileal pouch advancement and neoileoanal anastomosis has been described in two patients[11]. The technique is similar to that employed for the treatment of complex pouch-anal fistula[20].

Outcome

Postoperative morbidity was encouragingly low despite the complex nature of these repeat procedures. Anal sphincter function was also good despite the second attempt at IPAA. Great care was taken in each case, however, to identify the sphincter and dissect cautiously in the plane between any residual mucosa and the muscle. Six of the 17 patients with successful operations continue to experience less than perfect continence with occasional seepage (four patients) or the need to wear a pad (two). Even these patients are more than satisfied with the functional outcome.

In conclusion, disconnection, pouch revision and repeat IPAA can be accomplished safely with a good prospect of success. The indications for surgery can be summarized as poor initial surgical technique and problems of a 'mechanical' nature, while sepsis (and Crohn's disease) appear to be the major contraindications.

Short note

Low malignant potential of the double-stapled ileal pouch–anal anastomosis

The operative treatment of ulcerative colitis has changed with the development of the stapled technique of pouch construction and the procedure of double-stapled ileal pouch–anal anastomosis (IPAA). This technique is being used at many specialist centres as the procedure of choice for restorative proctocolectomy (RPC) for ulcerative colitis because of its many advantages, including a shorter operating time, a comparatively easier technique owing to the omission of the mucosectomy, a lower rate of pelvic sepsis and also some evidence that the reduced anal manipulation and preservation of the anal transitional zone mucosa lead to a better functional outcome. However, the major theoretical disadvantage of this technique is the possible development of dysplasia and eventually carcinoma in the retained mucosa. The aim of this study was to evaluate this risk of dysplasia in the retained anal mucosa in patients with ulcerative colitis who underwent RPC with a double-stapled IPAA without mucosectomy.

Patients and methods

The records of 109 patients who underwent RPC with non-mucosectomy double-stapled IPAA for ulcerative colitis from September 1988 to December 1993 were reviewed. A minimum follow-up of 1 year was obtained. Patients who had IPAA for any condition other than ulcerative colitis were excluded, as were those with ulcerative colitis who were found to have carcinoma or dysplasia in the colon at the time of surgery. The histology of the distal rectal doughnut as well as the follow-up biopsies were reviewed by one of two pathologists. Follow-up studies included clinical evaluation with digital examination, endoscopy and random 2-mm pinch biopsies of the retained mucosal cuff. These biopsies were undertaken at the time of ileostomy closure and then annually, and any dysplasia was noted and graded. If the doughnut and two consecutive biopsies revealed squamous epithelium, further follow-up biopsies were not performed.

Results

There were 69 men (mean age 42·5 (range 14–72) years) and 40 women (mean age 37·5 (range 23–71) years). A total of 109 rectal doughnuts were reviewed. During follow-up of 1–6 (mean 2·6) years, a total of 186 biopsies of the anal mucosa were examined (mean 1·7 follow-up biopsies per patient; all patients had at least one biopsy). Only one patient was noted to have low-grade dysplasia in the distal rectal doughnut at the time of operation. Four follow-up biopsies of the retained mucosa in this patient over a period of 3 years, however, revealed no evidence of dysplasia. There was no recorded case of dysplasia in the follow-up biopsies of the retained mucosa in any patient in the series. No carcinomas were noted, either at the time of surgery or during the follow-up period.

Discussion

Double-stapled IPAA has become the procedure of choice in patients with ulcerative colitis after RPC. Ambroze *et al.*[1] have questioned the advisability of non-mucosectomy ileoanal reservoir because of the potential for malignant change in the retained mucosa. However, there have been no reports of carcinoma in the retained mucosal strip. Conversely, there have been several reports of viable rectal mucosa following mucosectomy[2]. The only major difference with respect to the risk of malignant disease is that, after mucosectomy, surveillance is difficult, while double-stapled IPAA without mucosectomy affords an opportunity to survey the mucosa regularly with visualization, palpation and biopsy[3]. Low-grade dysplasia in the distal rectal doughnut at the time of the original operation was noted in only one of 109 patients in this series. No dysplastic change was noted in any of the follow-up biopsies. Tsunoda *et al.*[4] reported a series of 118 patients with ulcerative colitis who underwent RPC: 110 had no carcinoma or dysplasia in the colectomy specimen. In this group, dysplasia was seen in the mucosal strippings of only one patient. This 0·9 per cent incidence is exactly the same as that noted in the present series. Ziv *et al.*[5] have reported a series of 254 patients who underwent non-mucosectomy stapled IPAA with a similar incidence of proven dysplasia of only 0·8 per cent. Schmitt *et al.*[3], in an earlier series from this department, reported on the first 51 patients (who are included in the present study) and found no dysplasia in any patient, either at the time of initial surgery or during a mean follow-up of 8·6 months. It appears, therefore, that the risk of malignant transformation in the strip of retained anorectal mucosa is slight and does not increase appreciably in the first few years after operation. The procedure of double-stapled IPAA without mucosectomy for patients with ulcerative colitis is quite safe.

Plasma from 33 patients at risk of multiple organ failure (MOF) after major trauma was tested for a priming effect on neutrophils, and for the presence of platelet-activating factor (PAF) activity and interleukin (IL) 8. Plasma sampled at 3, 6, 12 and 24 h after injury significantly primed normal neutrophils to release mean(s.e.m.) 1·26(0·19), 1·33(0·26), 1·04(0·14) and 0·86(0·13) nmol superoxide per min per $1{\cdot}3 \times 10^6$ neutrophils respectively ($P < 0{\cdot}05$). Priming at 3 h after injury was inhibited by mean(s.e.m.) 63·8(7·0) per cent by the PAF antagonist, WEB 2170 ($P < 0{\cdot}01$). Mean(s.e.m.) plasma IL-8 was raised at 6 and 12 h after injury to 785(183) and 836(175) pg/ml ($P < 0{\cdot}01$). At 12 h after injury the plasma IL-8 level correlated directly with the number of units of red blood cells transfused ($r = 0{\cdot}64$, $P < 0{\cdot}01$), and was significantly higher in the group of six patients who developed MOF ($P < 0{\cdot}05$). These data suggest that after trauma the mediators PAF and IL-8 appear sequentially in the circulation, are potential mechanisms of circulating neutrophil priming, and that IL-8 may also be an early biochemical marker predicting the onset of MOF.

Polymorphonuclear neutrophils are important effector cells in the systemic inflammatory response syndrome, a premonitor of multiple organ failure (MOF)[1,2]. Priming of neutrophil adhesion and superoxide generation are prerequisites for neutrophil sequestration and tissue injury[3,4]. Previous studies have revealed that circulating neutrophils are endogenously primed for enhanced superoxide anion release and β_2-integrin expression within hours after a major injury[4,5]. The first 24 h after trauma is therefore a vulnerable window for neutrophil-mediated end-organ injury, especially when these primed and sequestered neutrophils are subjected to an activating stimulus. However, little is known about the kinetics and mechanisms of neutrophil priming during this vulnerable period.

In contrast to 'flow' phase catabolic changes after injury that are caused by stress hormones, 'ebb' or acute phase changes are thought to be due to specific mediators, which include platelet-activating factor (PAF), eicosanoids and cytokines[6–8]. PAF and the cytokine interleukin (IL) 8 are particularly important because of their priming effect on neutrophils and their potential role in the development of a systemic inflammatory response and MOF[7,9–11]. *In vitro* experiments have shown both PAF and IL-8 to be potent and rapid primers of neutrophil superoxide release[4,12,13]. During intestinal ischaemia–reperfusion in a rat model, designed to mimic the splanchnic hypoperfusion experienced after major trauma, there is a fivefold increase in PAF in the gut mucosa and portal blood, and circulating PAF has been implicated in causing both neutrophil priming and the systemic shock response[9,14–16]. In addition to endogenous PAF production, PAF-like lipids are also found in large quantities in transfused blood products[17,18]. Blood products also contain substantial amounts of cytokines such as IL-6 and IL-8[19,20]. In addition, cytokines are produced endogenously by several cell lines after injury[10]. The kinetics of systemic release of PAF and IL-8 after injury have not been studied, but in a human blister fluid model of local skin trauma, expression of PAF-like lipids preceded IL-8 by several hours, suggesting a sequential release of lipid and cytokine mediators after injury[21].

Victims of major trauma suffer mechanical tissue injury and ischaemia–reperfusion injury due to shock, as well as receive substantial transfusion of blood products. This study was therefore designed to investigate whether plasma from patients with major trauma contains mediators that prime neutrophils, whether PAF activity in the plasma precedes IL-8, and whether PAF activity and/or IL-8 levels are increased in patients who ultimately develop MOF.

Patients and methods

In a previous epidemiological study, age greater than 55 years, Injury Severity Score (ISS) above 25 and a transfusion requirement of more than 6 units of red blood cells within the first 12 h of injury, were identified as independent risk factors for the development of MOF[22]. For this laboratory study, between April 1993 and August 1994, only patients (1) aged between 18 and 55 years, (2) who had major trauma to the torso requiring a laparotomy within the first 3 h of admission, and (3) who had an ISS of 25 or more, or an ISS above 15 associated with transfusion of 6 or more units of blood within the first 12 h, were included. Patients with pre-existing organ dysfunction or major head injury (i e with a Glasgow Coma Scale (GCS) score below 8) were excluded. From day 3 after trauma, pulmonary, renal, hepatic and cardiac function were graded daily using a clinical and laboratory based scoring system from 1 to 4 for each organ. MOF is defined as a total organ dysfunction score greater than or equal to 4, with two or more dysfunctional organs[22]. Demographic, risk factor and outcome variables were collected and included: (1) host factors (sex, age, pre-existing disease); (2) tissue injury (ISS, GCS); (3) clinical signs of ischaemia–reperfusion (judged from systolic blood pressure in the emergency department, red blood cell transfusion within the first 12 h of injury, serial blood lactate levels and base deficit); and (4) outcome (septic and non-septic complications, duration of mechanical ventilation, length of stay on the surgical intensive care unit (ICU), MOF, death). Written informed consent was

Paper accepted 6 June 1996

obtained from all patients, or next of kin, before enrolment. Ten healthy adult volunteers served as normal controls.

Plasma priming

Blood sampling. Central venous blood from patients and peripheral venous blood from volunteers was collected in chilled tubes containing ethylenediamine tetra-acetic acid and immediately centrifuged at 1000*g*. The plasma was stored at −70°C and thawed to 37°C only once before use in experiments. Normal neutrophils were obtained by sampling peripheral blood from healthy volunteers in heparinized glass tubes at room temperature.

Separation of neutrophils Slight modifications of the original technique described by Boyum *et al.*[23] were employed. Briefly, heparinized blood was layered over a sodium metrizoate/Dextran 500 solution (PMN; Robbins Scientific Corporation, Sunnyvale, California, USA) and centrifuged at 400*g* for 30 min at room temperature. Contaminating erythrocytes were removed by hypotonic lysis, and neutrophils were washed twice in 0·9 per cent sodium chloride and resuspended in 0·1 per cent dextrose in Dulbecco's phosphate-buffered salt solution (Cellgro; Mediatech, Herndon, Virginia, USA). Purity and viability (tested by trypan blue dye exclusion) of neutrophil preparations were above 95 per cent

Incubation time Plasma obtained in the first 24 h after injury from the first four patients was used to determine the shortest incubation time in which plasma would prime neutrophils. Priming was defined as enhanced neutrophil superoxide release after stimulation with *N*-formyl-methyl-leucyl-phenylalanine (fMLP). Neutrophils from volunteers were suspended in buffer and incubated for 5, 15, 30 and 60 min in an equal volume of patient plasma at a final concentration of 1×10^7 neutrophils/ml). After incubation, aliquots of the mixture were transferred to a microplate and neutrophil priming for superoxide release assessed

Measurement of superoxide anion release Extracellular release of superoxide was measured using a THERMOmax microplate reader supported by SOFTmax software (Molecular Devices, Menlo Park, California, USA) as described previously[4]. Ferricytochrome c, superoxide dismutase (SOD) and fMLP were purchased from Sigma Chemical Company, St Louis, Missouri, USA. Each assay of neutrophil superoxide production was performed in duplicate microtitre plates that contained $1 \cdot 3 \times 10^6$ neutrophils/ml (i.e. 2×10^5 cells/well) and ferricytochrome c 75 μmol/l in a final volume of 150 μl. In addition, SOD 100 μg/ml was added to the reaction mixture of a third well to measure SOD-inhibitable ferricytochrome c reduction. Neutrophils were kept in suspension by automated shaking of the microtitre plate just before each spectrophotometric reading. Dual beam spectroscopy at 550 nm and 450 nm commenced on addition of fMLP 1 μmol/l. Readings continued every 20 s for 10 min. The reaction mixture was maintained at 37°C, and data were plotted kinetically as the maximum velocity (V_{max}) of the reaction V_{max} was calculated for five readings and expressed as a change in optical density per minute An extinction coefficient of 8400 l/mol for ferricytochrome c (path length 0·4 cm) was used to convert V_{max} results to nmol superoxide per min per $1 \cdot 3 \times 10^6$ neutrophils.

Time course after injury Neutrophils from volunteers were incubated for 5 min in heterologous control plasma, as well as plasma sampled from the first 22 patients at 3, 6, 12, 24, 48, 72, 96 and 120 h after injury. Neutrophil priming was measured thereafter as described above.

WEB 2170 inhibition of plasma priming. To test whether the priming of healthy control neutrophils by plasma from patients with trauma was by a mechanism involving PAF, WEB 2170 (Boehringer-Ingelheim Pharmaceuticals, Ridgefield, Connecticut, USA), a PAF antagonist, was used. Plasma from ten patients with trauma who had an ISS of 25 or more and had plasma samples available for all four time points during the first 24 h was used. Neutrophils from healthy volunteers were pretreated with either WEB 2170 400 μmol/l or buffer for 5 min. Plasma from either a patient or heterologous volunteer at a dilution of 1 · 10 was then added before incubation for a further 5 min. Neutrophils from each of the four tests were pelleted by centrifugation at 1000*g* for 2 min and resuspended in buffer. The neutrophils were then transferred to a microplate and superoxide release measured in response to fMLP 1 μmol/l. Modification of the protocol, i.e. additional centrifugation to separate neutrophils from the priming plasma, resulted in higher recorded amounts of superoxide released than during the original plasma priming experiments.

Plasma interleukin 8

IL-8 levels were determined in the plasma of the first 31 patients enrolled into the study by a commercial sandwich enzyme-linked immunosorbent assay (Bender Medsystems, Vienna, Austria) The primary antibody was a monoclonal mouse immunoglobulin G, and the secondary antibody a horseradish peroxidase-conjugated, polyclonal rabbit antibody. Recombinant 72-amino-acid IL-8 was used to calculate the standard curve.

Statistical analysis

All data are presented as mean(s.e.m.). Demographic data were compared with Student's *t* test or Fisher's exact test. Comparison between control and patients' plasma priming for superoxide release at each time point after injury was with an unpaired *t* test. IL-8 levels at the different time points were compared by analysis of variance. Multivariate regression analyses were performed by treating all variables as continuous and using the computer program SPSS 6.12 (Statistical Package for the Social Sciences, Chicago, Illinois, USA).

Results

Of 52 eligible patients nine were lost because laboratory support staff were not available, and ten because informed consent could not be obtained within 3 h of admission. *Table 1* compares the demographic data, risk factors for MOF and clinical outcomes of enrolled *versus* non-enrolled patients; there were no statistically significant differences apart from increased blood transfusion requirement in the enrolled group. Mean (range) age of enrolled patients was 28 (18–55) years and they were predominantly male. Injuries were equally distributed between blunt (16) and penetrating (17) mechanisms. ISS ranged from 16 to 57, while transfusion requirement in the first 12 h varied from 0 to 49 units of packed red blood cells. There was no correlation between ISS and the amount of blood transfused ($r = 0 \cdot 02$, $P = 0 \cdot 90$). Of the 33 patients studied, seven developed MOF. Patients who developed MOF were more severely injured ($P = 0 \cdot 05$), received a larger blood cell transfusion, and had more septic and non-septic complications, longer admissions to the ICU and a higher mortality rate ($P < 0 \cdot 01$, *Table 2*).

Plasma priming

Incubation time. Plasma sampled from patients with trauma and incubated with neutrophils from normal volunteers for 5 min primed the neutrophils significantly more than plasma sampled from heterologous volunteers (mean(s.e.m.) 1·36(0·10) *versus* 0·56(0·06) nmol superoxide per min per $1 \cdot 3 \times 10^6$ neutrophils, $P < 0 \cdot 01$).

Incubation of normal neutrophils in patients' plasma for 15 min (mean(s.e.m.) 1·36(0·13) *versus* 0·54(0·07) nmol/min), 30 min (1·20(0·09) *versus* 0·52(0·10) nmol/min) and 60 min (1·21(0·12) *versus* 0·53(0·09) nmol/min) also resulted in significant neutrophil priming ($P < 0·01$).

Time course after injury. Mean(s.e.m.) neutrophil priming by all patients' plasma sampled at 3 h after injury was 1·26(0·19) nmol/min, which was significantly more than that by control plasma ($P < 0·01$). Plasma sampled at 6 h (mean(s.e.m.) 1·33(0·26) nmol/min, $P < 0·01$), 12 h (1·04(0·14) nmol/min, $P < 0·01$) and 24 h (0·86(0·13) nmol/min, $P = 0·02$) after injury also significantly primed normal neutrophils, but plasma sampled after 24 h did not (*Fig. 1*). Neither age, sex, mechanism of injury, ISS, systolic blood pressure in the emergency department, number of units of red blood cells transfused, base deficit nor serum lactate level contributed significantly to the level of plasma priming. The level of plasma priming at 3 h was no different in patients who did or did not develop MOF (mean(s.e.m.) 2·21(0·76) *versus* 1·11(0·17) nmol/min, $P = 0·06$), 6 h (0·91(0·48) *versus* 1·43(0·30) nmol/min, $P = 0·44$), 12 h (1·15(0·34) *versus* 1·00(0·15) nmol/min, $P = 0·69$) or 24 h (1·17(0·25) *versus* 0·75(0·14) nmol/min, $P = 0·16$) after injury.

WEB 2170 inhibition of plasma priming. In this experiment, normal donor neutrophils incubated in heterologous control plasma released mean(s.e.m.) 3·6(0·3) nmol/min. Pretreatment of neutrophils with WEB 2170 before incubation with heterologous donor plasma did not decrease superoxide release (mean(s.e.m.) difference 2·7(6·5) per cent, $P = 0·85$). Priming by patients'

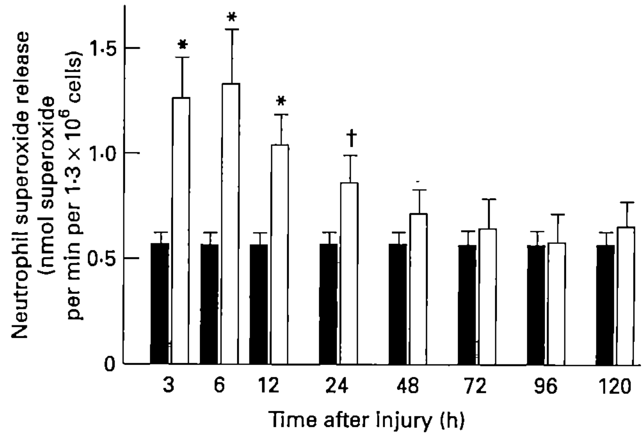

Fig. 1 Time course after injury of normal neutrophil priming by plasma from patients with trauma. Neutrophils from healthy volunteers were incubated for 5 min in either heterologous control plasma (■) or plasma from patients (□) sampled at 3, 6, 12, 24, 48, 72, 96 and 120 h after injury. After incubation, neutrophil superoxide release was measured in response to N-formyl-methyl-leucyl-phenylalanine 1 μmol/l to test for neutrophil priming. Values are mean(s.e.m.). *$P < 0·01$, †$P = 0·02$ *versus* control (unpaired t test)

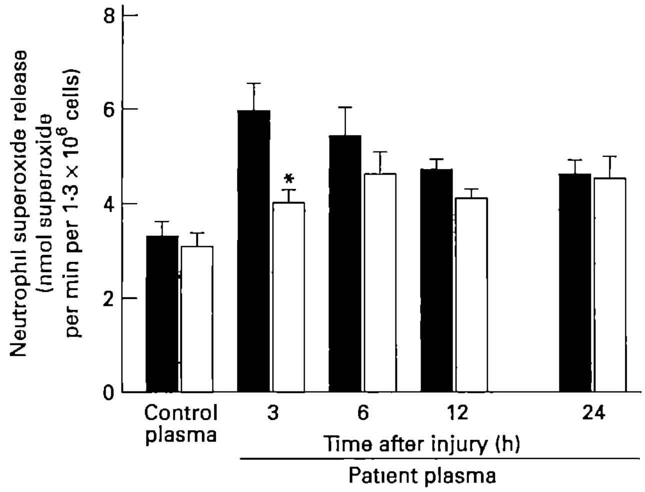

Fig. 2 WEB 2170 (a platelet-activating factor antagonist) inhibition of plasma priming. Neutrophils from healthy volunteers were pretreated with either buffer (■) or WEB 2170 (□) before incubation for 5 min in either heterologous control plasma or plasma from patients sampled at 3, 6, 12 and 24 h after injury. After incubation, neutrophil superoxide release was measured in response to N-formyl-methyl-leucyl-phenylalanine 1 μmol/l to test for neutrophil priming. Values are mean(s.e.m.) $^*P<0{\cdot}01$ (paired t test)

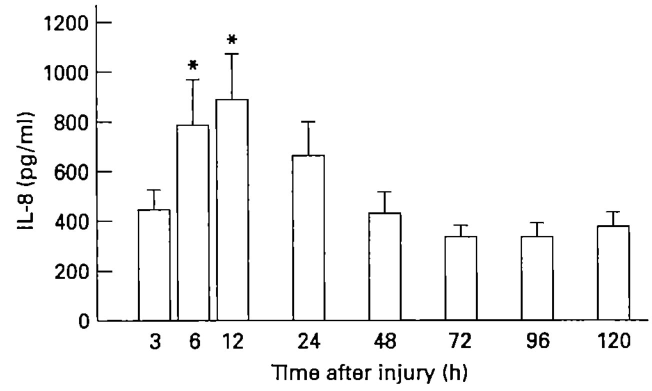

Fig. 3 Plasma interleukin (IL) 8 levels after injury. Values are mean(s.e.m.). $^*P<0{\cdot}05$ *versus* 72 and 96 h (analysis of variance)

plasma sampled at 3 h after trauma was inhibited by 63·8(7·0) per cent by WEB 2170 pretreatment ($P<0{\cdot}01$). WEB 2170 did not significantly inhibit priming by patients' plasma sampled at 6 h (mean(s.e.m.) inhibition 19·8(15·5) per cent), 12 h (30·1(15·7) per cent) and 24 h (9·2(20·1) per cent) after trauma ($P>0{\cdot}05$) (*Fig. 2*).

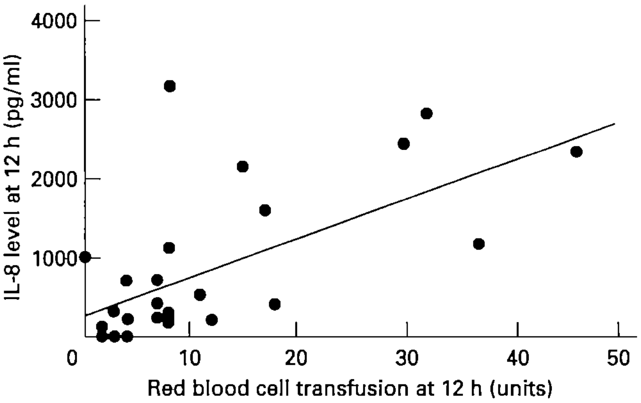

Fig. 4 Correlation between plasma interleukin (IL) 8 level and units of red blood cells transfused at 12 h after major trauma ($r=0{\cdot}64$, $P<0{\cdot}01$)

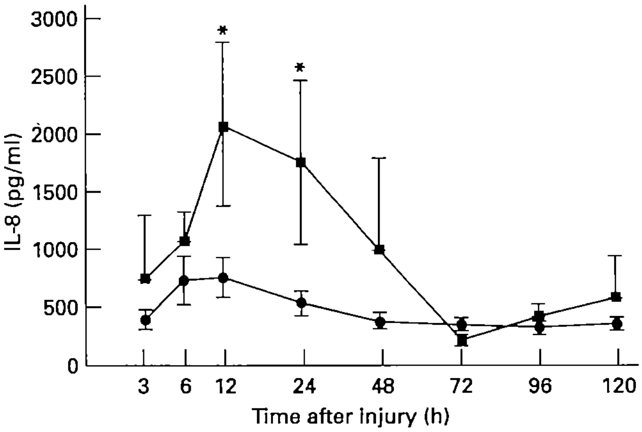

Fig. 5 Plasma interleukin (IL) 8 levels in patients who did (■) and did not (●) develop multiple organ failure (MOF). Values are mean(s.e.m.). $^*P<0{\cdot}05$ (MOF *versus* no MOF, analysis of variance)

Interleukin 8 levels after injury

Mean(s.e.m.) plasma IL-8 levels at 6 and 12 h after trauma were significantly increased to 785(183) and 836(175) pg/ml compared with the levels of 328(47) and 333(54) pg/ml at 72 and 96 h respectively ($P<0{\cdot}05$; *Fig. 3*). When plasma IL-8 levels at 12 h after trauma were correlated univariately with the recorded demographic data and risk factors for MOF, sex ($r=0{\cdot}58$, $P<0{\cdot}01$), lactate level at 12 h ($r=0{\cdot}54$, $P<0{\cdot}01$) and units of red blood cells transfused ($r=0{\cdot}64$, $P<0{\cdot}01$; *Fig. 4*) correlated significantly. However, in a stepwise multivariate analysis, units of red blood cells transfused was the only variable remaining in the equation to predict the plasma IL-8 level ($P<0{\cdot}01$). In the six patients who developed MOF, mean(s.e.m.) plasma IL-8 levels at 12 and 24 h after injury were 2081(715) and 1754(715) pg/ml respectively, and were significantly higher than those of 754(174) and 535(102) pg/ml in patients who did not develop MOF ($P<0{\cdot}05$; *Fig. 5*). In a stepwise multivariate analysis using all variables correlating with MOF ($P<0{\cdot}2$), i.e. ISS, mechanism of injury, lactate level, red blood cell transfusion, neutrophil count and plasma IL-8 level, only plasma IL-8 remained in the equation to predict MOF ($P<0{\cdot}01$).

Discussion

The terms 'ebb phase' (immediately following injury) and 'flow phase' (approximately 24 h to 7 days after injury) have been used to describe the changes in metabolism after injury[6]. The flow phase is the result of increased secretion of 'stress' or counter-regulatory hormones, such as catecholamines, cortisol, glucagon, growth hormone and insulin, resulting in increased gluconeogenesis, catabolism of muscle protein, protein and urinary nitrogen excretion, oxygen consumption and resting energy expenditure[7]. However, these hormones do not account for the ebb phase changes such as the haemodynamic shock response, decrease in level of proteins such as albumin, prealbumin and fibrinogen, or the increase in acute phase proteins such as C-reactive protein, fibrinogen and antiproteases[7]. Nor can the changes be explained by neuronal stimulation alone. Various 'mediator' groups of substances have been added to the historically well established hormones and neurotransmitters. These mediators are defined as communication molecules derived from one cell type that act on another by virtue of specific receptors, and are intermediate in lifespan between the long-lived hormones and the short-lived and locally acting neurotransmitters[7,8]. Their action is limited by effective control or removal processes in the tissues. Mediators, which include PAF, eicosanoids and cytokines, have been proposed as the substances responsible for the ebb or acute phase changes after injury. To prevent or limit acute phase changes and injury to end organs such as the lungs, it is crucial that the exact nature and timing of inflammatory mediator release early after major trauma is elucidated. Of particular importance are mediators with proinflammatory effects on neutrophils since neutrophils have been identified as central effector cells in acute end-organ injury and MOF after trauma. The authors have previously shown priming and activation of circulating neutrophils during the first 24 h after major trauma[4].

Data from this study show that plasma sampled from patients with major torso trauma at 3, 6, 12 and 24 h after injury contained mediators that primed normal neutrophils. The fact that plasma primed normal neutrophils very rapidly (within 5 min) excludes most protein mediators, as well as endotoxin which primes in 30 min, and points towards lipid mediators such as PAF or IL-8 as the plasma priming agents[13,23–25]. Plasma priming at 3 h after injury was inhibited by WEB 2170, indicating that priming was via a mechanism involving PAF, but priming from 6 to 24 h was not inhibited by WEB 2170. Although WEB 2170 is not absolutely specific for PAF, this bioassay provides a strong indication that PAF was present in the plasma at 3 h after trauma, and that from 6 to 24 h different mediators, e.g. complement fragments, IL-6 and IL-8, were responsible for plasma priming. Direct measurement of PAF in the plasma is difficult and labour intensive, but will be required to identify PAF beyond any doubt. Plasma IL-8 levels were increased at 6 and 12 h after injury. Thus, as in models of local inflammation, IL-8 appeared in the circulation some hours after PAF. Interestingly, plasma IL-8 level at 12 h after injury correlated directly with the number of units of red blood cells transfused up to that point. Plasma IL-8 was two and a half times higher in patients who went on to develop MOF, and remained raised until 24 h after injury in these patients. Plasma IL-8 level at 12 h after injury is a better predictor of MOF than ISS, red blood cell transfusion or plasma lactate level. Neutrophil priming by plasma from patients who developed MOF was not different from that in those who did not, which may indicate that priming by IL-8 is a threshold rather than linear phenomenon.

The most likely sources of circulating mediators such as PAF and IL-8 after major trauma are direct mechanical tissue injury, ischaemia–reperfusion of tissue beds and blood transfusion. After mechanical injury, humoral mediators are released to effect a local inflammatory response but also spill over into the systemic circulation[7,26]. Resuscitation of trauma victims after variable periods of haemorrhagic shock may result in ischaemia–reperfusion injury, particularly in the gut which undergoes disproportionate vasoconstriction[27]. During ischaemia, phospholipase A_2 is activated which in turn results in the release of PAF[16]. Reperfusion of ischaemic tissues leads to the generation of free radicals and other reactive oxygen metabolites which are potent proinflammatory stimuli, and results in the release of prostaglandins, leukotrienes, PAF and cytokines, as well as promoting neutrophil–endothelial cell interaction[14,16,27,28]. Major blood transfusion can be associated with acute lung injury as well as delayed immunosuppression and infectious complications after surgery[19,27]. The mechanisms of transfusion-induced end-organ injury as well as immunosuppression remain largely unclear, but the fact that stored autologous and allogeneic blood have similar immunosuppressive effects points to the storage procedure as a significant factor[29]. Of particular importance is the leucocyte count and leucocyte release of cytokines in stored blood products. Nanomolar amounts of cytokines, including IL-8, have been detected in stored platelet concentrates, with lower levels in stored red blood cells[30]. Stored blood components also contain proinflammatory mediators similar to PAF[18]. These proinflammatory mediators can prime circulating neutrophils as well as stimulate endothelial cells, thereby promoting neutrophil sequestration in uninjured end organs, and setting the stage for neutrophil-mediated end-organ injury[31,32].

Clinical studies attempting to eliminate individual mediators responsible for acute inflammation-induced end-organ injury have met with some success. Marzi *et al.*[33] used systemic superoxide dismutase in patients with major trauma to limit free radical damage. PAF receptor antagonists have been used in the clinical settings of acute pancreatitis, sepsis and post-transplant renal failure[34–36]. Also on the horizon are bradykinin receptor antagonists[37]. Anticytokine studies have been less successful. Soluble receptors for tumour necrosis factor (TNF) α have been cloned and administered parenterally in an attempt to neutralize TNF-α and prevent neutrophil activation[38]. Current trials are under way to test anti-IL-6 strategies in sepsis and burns. However, numerous inflammatory cascades and mediators are released after trauma and it is therefore unlikely that use of a single agent would be effective in preventing neutrophil-mediated end-organ injury. Safety in transfusing allogeneic blood products is continuously being improved, and reducing the amount of leucocytes and leucocyte products in packed red cell and platelet concentrates may prove crucial in reducing many of the immunological side-effects of a major blood transfusion[39].

In conclusion, this preliminary study has shown that PAF activity and IL-8 are expressed sequentially in the circulating plasma within hours after major trauma. PAF and IL-8 may be the mediators responsible for priming of neutrophils in these patients at risk of MOF. Plasma IL-8 levels correlated directly with the number of units of red blood cells transfused, and may be an early biological marker of patients who are likely to develop MOF after trauma.

Conservative management of infective mastitis and breast abscesses after ultrasonographic assessment

R. J. O'HARA, S. P. L. DEXTER and J. N. FOX

Department of Surgery, Hull Royal Infirmary, Hull, UK
Correspondence to. Mr J. N. Fox, Castle Hill Hospital, Castle Road, Cottingham HU16 5JQ, UK

Current practice in this unit for a suspected breast abscess is preliminary ultrasonographic scan, aspiration of any pus, antibiotic therapy and repeat aspiration in the outpatient clinic if necessary. Inflammatory masses are treated with antibiotics alone. A retrospective review of this strategy has been made. Over a 2-year interval 53 patients were admitted to hospital with a suspected breast abscess. Twenty-two abscesses were aspirated, of which 19 resolved and three required subsequent incision and drainage. Eight patients underwent primary incision and drainage, one of whom required a second drainage procedure. In five patients the abscess discharged spontaneously before intervention. The remaining 18 patients were found on ultrasonography to have inflammation without evidence of focal pus which settled with antibiotic therapy in all but two patients. One of these was found to have an inflammatory cancer and the other developed an abscess, which was drained. Aspiration combined with ultrasonographic imaging is an effective alternative to incision and drainage.

The conventional treatment of a breast abscess is incision and drainage[1]. This usually requires a general anaesthetic, possibly an overnight stay in hospital and regular dressing. In the lactating patient this causes distress to both mother and baby. The incision may also produce an unsatisfactory cosmetic result. In non-lactating abscesses, most of which are related to periductal mastitis, incision and drainage may be associated with recurrence and mammary duct fistula[2].

Aspiration of pus combined with antibiotic therapy is another option[3]. However, breast abscesses may be multilocular and inadequately drained by aspiration[4]. The role of ultrasonographic imaging in the assessment of a suspected breast abscess is established and the technique can be used to assess the adequacy of pus aspiration[5].

Current practice in this unit for a suspected breast abscess is an ultrasonographic scan to demonstrate the presence or absence of pus, aspiration under ultrasonographic guidance or after skin marking, antibiotic therapy and outpatient follow-up for repeated aspiration, if necessary. Inflammatory masses without evidence of pus are treated with antibiotics alone. A retrospective review has been performed of this strategy.

Patients and methods

Records of all patients admitted to the surgical acute admissions ward of the Hull Royal Infirmary between January 1993 and December 1994 with a provisional diagnosis of breast abscess were reviewed Special note was made of the use of diagnostic ultrasonography, the technique and outcome of intervention, and the occurrence of any complications.

The treatment of individual patients during the study was dependent on the admitting surgical team. This accounts for the variability in the use of ultrasonography and of primary aspiration or surgical drainage of pus.

Results

Over the 2 years 53 women were seen with a suspected breast abscess. Details of the patients are shown in *Table 1*. Some 36 women (68 per cent) had an ultrasonographic scan as part of their initial management, while the remainder were treated according to clinical features alone. In seven cases this included 'blind' aspiration.

No focal collection was seen in 19 of the 36 women who had a scan. One of these scans was falsely negative. One woman clinically had an abscess, despite the findings on ultrasonography, and had immediate incision and drainage. There were no false-positive scans. The sensitivity was therefore 95 per cent and the specificity 100 per cent.

In the series of 53 patients, 35 (66 per cent) were found to have an abscess and 18 (34 per cent) had inflammatory change with no focal collection, using ultrasonographic and clinical evidence. Sixteen of the 18 patients with inflammation alone settled with antibiotic treatment and no further intervention. Of the two patients whose symptoms did not resolve, one developed an abscess after 3 days of antibiotics and was considered a treatment failure. This was incised surgically and subsequently healed. The other patient in this group was found to have an inflammatory cancer, which was confirmed by fine-needle cytology. Twenty-two patients underwent aspiration; nineteen abscesses were treated successfully, although one patient developed a persistent sinus which eventually settled without intervention. In two patients delayed surgical drainage was required. One refused repeat aspiration and required incision and drainage of the residual abscess. One further abscess did not settle with aspiration and 200 ml pus were subsequently drained by formal incision.

Of eight patients treated by primary incision and drainage, one required further surgical drainage and one

Table 2 Isolation of bacteria from breast abscesses

Bacterial growth	Lactational abscess	Non-lactational abscess
Staphylococcus aureus	9	6
S. aureus and diphtheroids	—	1
S. epidermidis	—	3
Bacteroides spp.	—	3
Bacteroides spp. and peptostreptococcus	—	2
Bacteroides spp. and *Proteus mirabilis*	—	1
P. mirabilis	—	4
No growth	—	3

has been left with a scarred deformity of the nipple. In five women the abscess drained spontaneously; four resolved without complication, but one patient developed a mammary duct fistula. Four of the five were treated with antibiotics.

Whereas pus from lactational abscesses grew exclusively *Staphylococcus aureus*, a variety of organisms were isolated from non-lactational abscesses (*Table 2*).

Nine of 17 lactational infections were initially considered inflammatory on ultrasonography. Eight of these responded to antibiotics alone, but one patient returned after 3 days with an abscess.

Discussion

This retrospective review of 53 patients with the clinical features of a breast abscess demonstrated that 18 patients (34 per cent) did not have a collection of pus. An ultrasonographic scan therefore could prevent about one-third of patients undergoing unnecessary surgical intervention.

Management based on ultrasonographic findings led to failure of conservative treatment in only four of 36 patients. In one of these the scan was falsely negative and the abscess was drained. In a second, antibiotics failed to resolve the lesion and an abscess developed after 3 days. In the other two shown to have a collection of pus, aspiration of a very large abscess was probably inadequate in one patient, and the second patient declined further aspiration on the grounds of discomfort of the procedure. Whilst some patients experience discomfort during the procedure, prior application of local anaesthetic (EMLA) cream reduces pain and makes aspiration acceptable.

Blind aspiration without ultrasonographic imaging was done in seven patients, usually when the abscess was superficial and easy to localize. In one case this failed, underlining the usefulness of ultrasonographically-guided aspiration.

The finding of an inflammatory cancer emphasizes the need for follow-up imaging and, if necessary, fine-needle cytology on patients with inflammatory breast conditions before discharge from the clinic.

Thirty-six breast infections (68 per cent) were non-lactational. The range of bacteria isolated from the abscesses confirms the need to use broad-spectrum antibiotics active against anaerobic activity, rather than the traditional antistaphylococcal antibiotic therapy[6].

Although incision and drainage has been regarded as appropriate treatment for breast abscess, aspiration is an effective alternative. Assessment by ultrasonography confirms the need for intervention and facilitates aspiration. The combined use of ultrasonographic imaging and aspiration should enable almost all inflammatory breast conditions to be managed conservatively in the breast clinic.

Image-guided core biopsy in patients with breast disease

M. J. B. CHARE, C. I. FLOWERS*, C. J. O'BRIEN† and A. DAWSON†

*Departments of Surgery, *Radiology and †Pathology, Neath General Hospital, Neath and Breast Test Wales, Swansea, UK*
Correspondence to: Mr M. J. B. Chare, Neath General Hospital, Neath SA11 2LQ, UK

Ultrasonographically-guided core biopsy has been used as an adjunct to triple assessment when fine-needle aspiration cytology was inadequate or equivocal, if the overall assessment of the patient was uncertain, or if it was deemed the preferred diagnostic option. Some 143 of 2603 patients had a guided core biopsy, 125 to establish the diagnosis and 18 to obtain histology in cytologically proven malignancy. A diagnosis of malignancy was established in 43 of the 125 patients who had a diagnostic core biopsy. Some 45 patients with benign disease were either discharged or returned to follow-up on the basis of the core biopsy. The remaining 37 patients required surgical biopsy, of whom 13 had malignant and 24 benign disease. The overall positive predictive value for malignancy was 98 per cent. Experience with ultrasonographically-guided core biopsy shows that it can reduce the need for surgical biopsy in both benign and malignant conditions of the breast.

Triple assessment by clinical examination, mammography and fine-needle aspiration cytology (FNAC) is now established in the appraisal of patients with breast disease[1]. If the findings of the triple assessment accord, firm management recommendations may be made, otherwise surgical biopsy is usually required to establish the diagnosis. Image-guided core biopsy using stereotactic[2,3] or ultrasonographic[4] guidance is now used increasingly as an adjunct to triple assessment and may reduce the need for surgical biopsy.

Core biopsy with stereotactic guidance has been used mainly in the diagnosis of impalpable lesions, but needs expensive equipment and special expertise. Ultrasonographically-guided core biopsy, however, may be used in any specialist breast clinic using current ultrasonography equipment, without the need for major investment. This technique was used in the authors' breast clinics since August 1994, and experience gained to date is reported.

Patients and methods

The 2603 patients studied were seen by the breast team between 1 August 1994 and 31 January 1996. Some 2298 of these patients were referred to Neath Breast Clinic and the remaining 305 were seen in the Assessment Clinic at Breast Test Wales in Swansea. Both of these clinics are 'one-stop' clinics where the results of both breast imaging and clinical or image-guided FNAC are available during the clinic. A total of 125 of the 2603 patients underwent diagnostic ultrasonographically-guided core biopsy during the initial clinic visit. This was indicated if the cytology was inadequate C1 (30 patients) or equivocal C3 or C4 (41 patients), if the overall assessment of the patient was uncertain (20 patients), or if it was deemed the preferred diagnostic option (34 patients). In 18 patients it was used to obtain a histological diagnosis in a cytologically proven malignancy.

All procedures were performed under local anaesthetic with a 16-G needle with a 2·2-cm throw, using an automated core biopsy gun (Manan Promag 2·2; Kimal, Uxbridge, UK). Real time ultrasonographic visualization of the needle in the lesion at the time of the biopsy resulted in increased accuracy of sampling, even in clinically palpable lesions Care was taken to make sure the needle travelled parallel to the chest wall to avoid the possibility of pneumothorax, and at least three passes were made. Patients were seen in the clinic the following week with their results.

Image-guided core biopsy was considered the preferred alternative to cytology in 34 patients. Most commonly this was because the clinico-radiological findings were vague or diffuse suggesting lobular carcinoma or ductal carcinoma *in situ* (DCIS) (11 patients), if there was suspected recurrence in a conserved breast after radiotherapy (six) or if the patient was being considered for primary medical treatment (four). The procedure was used for patients re-referred to the clinic with the same clinical problem (seven patients) and also where there was a mass suggestive of a lipoma or fat necrosis (five), as in these conditions FNAC may show cells which are consistent with, but not diagnostic of, the pathology. In one patient the procedure was undertaken because bloodstained fluid was obtained during the aspiration of a complex cyst.

Results

Ultrasonographically-guided biopsy was well tolerated, although the degree of bruising noted by most patients was greater than that seen after FNAC. There were no significant side-effects following image-guided core biopsy.

The outcome of the 125 diagnostic core biopsies is summarized in *Table 1*. In 88 of the 125 patients undergoing diagnostic ultrasonographically-guided core biopsy a definite decision could be made regarding management; 43 patients had a diagnosis of malignancy and proceeded to primary treatment, and 45 patients with benign disease were discharged or returned to follow-up. A further ten patients elected to have the lesion excised despite benign assessment and benign core biopsy. The remaining 27 patients required surgical biopsy, of which 13 had malignant and 14 benign lesions.

Combining biopsies that were suspicious with those that were diagnosed as malignant resulted in a sensitivity of 80 per cent and specificity of 99 per cent. The positive predictive value for malignancy was 98 per cent, with a prevalence of 45 per cent. There were no 'true' false positives but one patient with a suspicious core biopsy had a benign papilloma and atypical hyperplasia. These figures for core biopsy are set against a high-quality FNAC service which has an absolute sensitivity for the same population of patients of 70 per cent.

Eighteen patients with a diagnosis of malignancy established by triple assessment also underwent ultrasonographically-guided core biopsy. In ten this was performed to assess the tumour type and grade before medical treatment, to exclude DCIS, which cannot be differentiated from invasive disease by cytology alone, and

Table 1 Outcome in 125 patients undergoing diagnostic core biopsy

Core biopsy histology	Clinical or radiological assessment	No.	Outcome	Final diagnosis after surgical biopsy
Malignant	Suspicious or malignant	43	Primary treatment	
Benign	Benign	45	Discharged/followed up	
Benign	Benign	10	Excision of lesion*	Benign 10
Suspicious of malignancy	Suspicious or malignant	3	Open biopsy	Benign 1† Malignant 2
Normal or benign	Uncertain or suspicious	24	Open biopsy	Benign 13 Malignant 11

*Lesions were excised at the patient's request despite an overall benign assessment; †histology was benign papilloma with associated atypical hyperplasia

to establish oestrogen receptor status in patients treated with tamoxifen alone. In two of the ten patients metastatic disease from a primary in the colon or lung was found. In the remaining eight patients with vague radiological findings or diffuse microcalcification, core biopsy confirmed either lobular carcinoma (four patients) or DCIS (four).

Discussion

Ultrasonographically-guided core biopsy is a safe technique that allows both palpable and impalpable lesions to be biopsied accurately during the patient's initial visit to the breast clinic. This accuracy makes the technique preferable to repeat FNAC when the result is inadequate or equivocal. This is achieved at little extra cost over that of FNAC, yet has the potential of greater than tenfold saving on the costs of a surgical biopsy.

Although ultrasonographically-guided core biopsy is of value only in patients whose radiological lesion is visible on ultrasonography, these results are comparable to those obtained using the prone table stereotactic digital imaging system for core biopsy[5]. Nevertheless, as lesions such as microcalcification, which are visible on mammography only, cannot generally be biopsied using this technique, the full potential of image-guided core biopsy can only be realized by the availability of both ultrasonography and stereotactic guidance in a breast clinic.

Experience with ultrasonographically-guided core biopsy shows that it is an inexpensive technique which can reduce the need for surgical biopsy for both benign and malignant conditions of the breast.

Use of covered expandable metal stents in the treatment of oesophageal carcinoma and tracheo-oesophageal fistula

T. A. COOK and T. C. B. DEHN

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to: Mr T. C. B. Dehn

Palliation for malignant dysphagia has relied on oesophageal dilatation, insertion of rigid prostheses and laser treatment. All three methods have substantial risk of perforation. Displacement of the tube is also well described. Seventeen expandable polyethylene-covered metal stents were inserted in 15 patients with oesophageal carcinoma; there were 11 men and four women, of median age 70 years. Thirteen stents were inserted for dysphagia and four for tracheo-oesophageal fistula (TOF). Stents were inserted endoscopically under fluorosopic control. Seven patients died from their disease a median of 5 (range 1–11) months after stent insertion. Median follow-up in the remainder is 6 (range 1–11) months. Median dysphagia scores before and after insertion were 3 (range 2–4) and 1 (range 1–2) respectively. Stent insertion provided cure of symptoms in patients with TOF. Median hospital stay following insertion was 2 (range 1–20) nights. There were no deaths and no perforations associated with the procedure. Two patients complained of retrosternal chest pain for 2 days after stent insertion. One patient presented with dysphagia related to later stent migration. There has been no deterioration in symptoms of dysphagia in the remainder. Expandable oesophageal stents offer a safe alternative to traditional methods of palliative treatment for oesophageal carcinoma. In the long term they may provide a cost-effective alternative to standard treatments.

Palliation of dysphagia may be the only treatment attainable in up to 60 per cent of patients with oesophageal carcinoma[1]. The life expectancy of patients with irresectable oesophageal tumours is measured in months. Successful palliation should achieve effective relief of dysphagia with both minimal risk and short hospital stay. The purpose of this study was to assess the effectiveness of covered expandable metal stents in achieving these goals and to determine the length of hospitalization in patients undergoing stent placement.

Patients and methods

Seventeen expandable polyethylene-covered metal stents (Cook, Letchworth, UK) were inserted in 15 patients with oesophageal carcinoma; there were 11 men and four women of median age 70 (range 52–89) years. There were two middle-third tumours, 12 lower-third lesions and one at an anastomosis in a patient who had undergone oesophagogastrectomy 17 months previously. There were two squamous cell carcinomas and the remainder were adenocarcinomas. Median tumour length was 5 (range 3–10) cm. Thirteen stents were inserted for dysphagia and four for tracheo-oesophageal fistula (TOF) Stents were inserted endoscopically, without prior dilatation, under fluoroscopic control. Assessment of swallowing was made by direct questioning on admission, at discharge and at 6-weekly follow-up using dysphagia scores (0, normal swallowing; 1, dysphagia to some solids, 2, tolerates semisolid diet only; 3, tolerates liquids only; 4, aphagia). Patients were followed until death

Results

Seven patients died from their disease a median of 5 (range 1–11) months after stent insertion. Median follow-up in the remainder is 6 (range 1–11) months. Median dysphagia scores before and after insertion were 3 (range 2–4) and 1 (range 1–2) respectively (*Fig. 1*). Stent insertion provided immediate cure of symptoms in the three patients with malignant TOF on four occasions (one man developed a second and more proximal TOF requiring a further stent). Median hospital stay following insertion was 2 (range 1–20) nights.

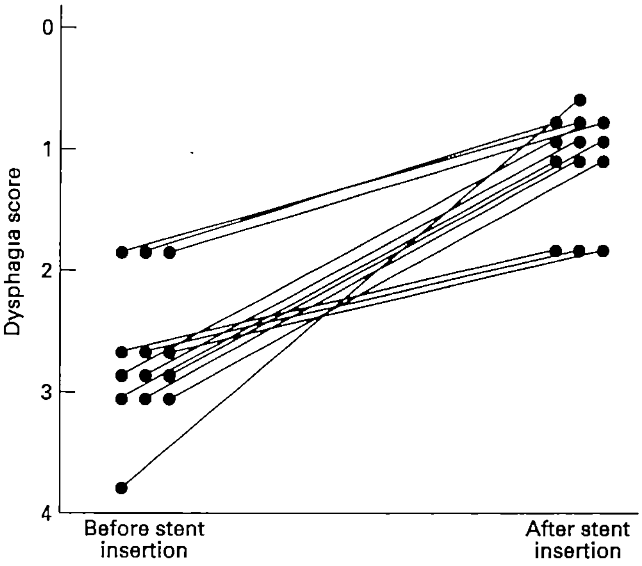

Fig. 1 Dysphagia scores before and after stent insertion

There were no deaths and no perforations associated with the stent insertion. Two patients complained of retrosternal chest pain for 2 days following the procedure but there were no other complications associated with insertion. One patient developed a TOF following radiotherapy for recurrent oesophageal tumour 4 months after stent insertion for relief of dysphagia. A second stent was inserted with successful control of TOF symptoms. This man developed a second and more proximal TOF and a third stent was successfully inserted. One patient suffered recurrent dysphagia: the stent had migrated

Stent	600
Total cost per patient	1200

distally into the stomach. This patient subsequently underwent laser therapy. There has been no deterioration in symptoms of dysphagia in the remainding patients. *Table 1* shows a breakdown of the cost of stent insertion. Median time for stent insertion (from patients entering to leaving the fluoroscopy room) was 48 (range 36–81) min.

During the period of study six other patients with oesophageal cancer, aged 55 (range 21–75) years, deemed irresectable on the grounds of comorbidity or metastatic disease, were palliated by other means: laser for bleeding tumours (three patients), chemotherapy (two) and radiotherapy (one).

Discussion

Palliation of oesophageal carcinoma has relied on radiotherapy (external beam or intracavitary) and endoscopic procedures (simple dilatation, alcohol injection, laser therapy and intraluminal oesophageal stenting). Laser treatment is effective but may require repeated hospital admissions[2,3]. It may be particularly suitable for treatment of short tumours[4]. Radiotherapy, while effective for squamous cell carcinoma, is less effective in palliating adenocarcinoma and relief of dysphagia may not occur for several weeks[5]. Rigid prostheses provide early symptomatic relief but are associated with a high rate of complications such as perforation and bolus obstruction and a procedure-related mortality rate of up to 6 per cent[6]. One-third of patients require further admission following radiotherapy or insertion of rigid prostheses[7].

Early results using uncovered expandable metal stents were encouraging but tumour ingrowth and recurrent dysphagia were reported[8,9]. These problems have been overcome by using a covered stent. In this series no patient presented with recurrent dysphagia due to tumour growth through or at the ends of the stent. It was found that improvement in dysphagia score was immediate and maintained over the follow-up period. There were no complications associated with insertion. Minimal dilatation (if any) of the tumour is necessary before inserting the 9-mm sheath through which the stent is introduced. Subsequent bolus obstruction is rare because the internal diameter of the stent is 16 mm compared with 12 mm in most rigid prostheses.

Despite the presence of a barb on the stent to aid fixation, distal stent migration occurred in one patient. This may be overcome by immediate balloon dilatation of the stent. It is advisable not to insert expandable stents across soft tumours or those through which the endoscope will pass readily because stent migration is more likely to occur in these patients. The retrosternal chest pain experienced by two patients was due to continuing expansion of the stent over 48 h after insertion. In both cases the pain was controlled with simple analgesics.

Use of rigid stents in the management of TOF has not been encouraging[10]. Early reports have suggested a role for expandable stents in the management of malignant TOF[11]. The authors' experience has shown that expandable stents provide rapid relief of symptoms of malignant TOF. Although inpatient stay was slightly longer than that for patients with dysphagia (3 *versus* 2 nights) it compared favourably with length of stay following conservative treatment.

This observational study has shown four major benefits of expandable stents. First, hospital stay is short (2 nights in the majority of patients although social circumstances required a 20-night stay in one patient). This is shorter than overall hospital stay following rigid stent insertion (9 days)[8] or laser treatment (14 days)[3], or that in other series using expandable stents (4 days)[8,9]. Second, this method does not involve repeated trips to hospital which are required with radiotherapy or laser treatment. Third, there were no readmissions for bolus obstruction or tumour overgrowth. Finally, there was no procedure-related morbidity or death. Treatment of complications and repeated visits to hospital in an elderly group of patients have important cost implications. It is the authors' belief that the initial high cost of expandable stents is amply compensated by the short hospital stay and low procedure-related morbidity. The authors no longer use rigid stents in patients selected for palliation by stenting. Expandable stents may provide a more cost-effective means of palliation of oesophageal carcinoma than rigid stents, laser treatment or radiotherapy.

Port-site metastases in patients undergoing laparoscopy for gastrointestinal malignancy

T. A. COOK and T. C. B. DEHN

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to Mr T. C. B. Dehn

Laparoscopic colonic resection and laparoscopy for the assessment of malignant disease have been advocated. Metastatic deposits at port sites are recognized but the incidence of these is poorly defined. Forty-six patients, of median age 65 (range 19–90) years, with gastrointestinal malignancy underwent laparoscopy. Eighteen patients died a median of 4 (range 1–28) months after laparoscopy, four following colonic resection and 14 with gastro-oesophageal malignancy; ten had undergone resection. Median follow-up of the 28 survivors is 8 (range 2–39) months. Five of the 46 patients developed port-site recurrence giving an early incidence of port-site recurrence in this cohort of patients of 11 per cent. Five of 20 patients with tumour involving serosal surfaces developed port-site recurrence compared with none of 26 without serosal involvement ($P = 0.022$, Fisher's exact test). Port-site recurrence may be related to serosal involvement with tumour.

Abdominal wound metastases following laparotomy are rare[1]. While laparoscopic resection for colonic carcinoma remains controversial[2], laparoscopy for assessment and staging of upper gastrointestinal malignancies has gained wider acceptance[3–5]. Isolated case reports describe metastatic deposits at port sites and suggest that this occurs more commonly than following laparotomy[6]. Despite increasing awareness of port-site recurrence[6,7], the incidence is poorly defined. The purpose of this study was to determine the early incidence of port-site metastases and attempt to define factors relating to the tumour that might influence their occurrence.

Patients and methods

Between January 1992 and December 1995 laparoscopy was undertaken on 46 patients with gastrointestinal malignancy (median age 65 (range 19–90) years; 38 men, eight women). Patient data were collected prospectively. Five patients underwent laparoscopically-assisted colonic resection, four with known liver metastases, for control of local disease. Another had a single-port laparoscopy for small bowel obstruction immediately before laparotomy for an obstructing caecal carcinoma. The remainder, none of whom had a contraindication to resection on the basis of ultrasonography or computed tomography (CT) assessment, underwent laparoscopy for staging of gastric (ten patients) or oesophageal (30) carcinoma. Five-port laparoscopy was performed in these patients to allow inspection of the lesser sac and appropriate biopsy if indicated. Assessment was made of the presence of liver metastases, ascites, omental or peritoneal deposits and lymph node involvement. Twenty-eight patients subsequently underwent tumour resection. Patients were followed up until death.

Results

Eighteen patients died a median of 4 (range 1–28) months after laparoscopy. Four had had a colonic resection; all had advanced disease at the time of surgery. Eight patients with oesophageal malignancy died, seven of whom had undergone resection. Three of these patients died within 30 days, one from haemorrhage secondary to disseminated intravascular coagulation, one from sepsis resulting in multiorgan failure and one from anastomotic leakage. Six patients with gastric tumours died. Three had undergone resection; two of these patients died within 30 days, one from cardiac tamponade and one from complications of a tunnelled feeding jejunostomy tube. Median follow-up of the 28 survivors is 8 (range 2–39) months. Five of the 46 patients developed port-site recurrence.

Patients 1 and 2

A 71-year-old woman and 61-year-old man with gastric carcinomas were noted at laparoscopy to have a small volume of ascites and omental deposits undetected on preoperative imaging. Both underwent chemotherapy. Umbilical port-site recurrences developed 7 and 1 month later respectively. Both died 2 months later.

Patient 3

At laparoscopy a 19-year-old woman with a lower-third oesophageal adenocarcinoma was found to have liver secondaries, ascites and nodal secondaries. She underwent chemotherapy and initially had a good clinical, radiological and endoscopic response. She developed a port-site recurrence in the left upper quadrant after 10 months and is currently being treated with further chemotherapy.

Patient 4

A 59-year-old woman with known liver metastases underwent a laparoscopically-assisted anterior resection for an obstructing Dukes C carcinoma of the rectosigmoid. She had postoperative chemotherapy and developed a port-site recurrence at the umbilicus 9 months after surgery. She died 1 month later.

Patient 5

A 58-year-old man who had undergone a complicated appendicectomy as a child, presented with small bowel obstruction. A provisional diagnosis of adhesion obstruction was made and laparoscopy was performed via

---

Paper accepted 2 June 1996

a single port in the left upper quadrant; an obstructing caecal carcinoma was identified. At this stage, and before tumour manipulation, the operation was converted to an open right hemicolectomy. A Dukes B carcinoma with serosal tumour involvement was confirmed histologically. Fifteen months later the man presented with recurrent subacute bowel obstruction. At subsequent laparotomy a local recurrence was resected. A solitary nodule at the port site was also resected and shown to be metastatic tumour. The laparotomy wound was spared and there was no other peritoneal involvement of tumour.

Serosal involvement of tumour (primary tumour, omental or peritoneal deposits) was present in all five patients. Five of 20 patients with tumour involving serosal surfaces developed port-site recurrence compared with none of 26 without serosal involvement ($P = 0{\cdot}022$, Fisher's exact test).

Discussion

The incidence of port-site recurrence in this cohort of patients was 11 per cent. This is higher than that reported following laparotomy[1] or laparoscopy for gynaecological malignancy[8].

Laparoscopy is more accurate than CT or ultrasonography in detecting liver secondaries and omental or peritoneal tumour deposits[9]. While CT and ultrasonography may detect the presence of enlarged lymph nodes, five-port laparoscopy allows assessment of the degree of fixation and biopsies to be taken. None of the patients in this series had contraindications to laparoscopy on the basis of CT or ultrasonography.

Three factors that relate specifically to laparoscopic surgery may be important in the development of port site recurrence[6]. First, the repeated passage of instruments through the port may bring exfoliated cells adherent to the instrument into close proximity with the port site. Second, increased manipulation of the tumour, which is inevitable with the loss of tactile feedback using laparoscopic instruments, may lead to increased exfoliation of tumour cells. Finally, there are the effects of pneumoperitoneum. Clumps of whole cells have recently been collected in smoke produced by electrocoagulation at laparoscopy[10]. As gas escapes under pressure around port sites these clumps of tumour cells may be seeded into the wound.

Of the five patients with port-site recurrence, four had advanced disease at the time of laparoscopy but the fifth patient had a potentially curable caecal carcinoma. In this latter patient no manipulation of the tumour had been made at initial laparoscopy. The data suggest that port-site metastases may be related to serosal involvement of tumour. Port-site recurrences following resection of Dukes A tumours have been reported[11,12]. However, in one of these studies[11] a colotomy was performed, immediately exposing tumour cells to the peritoneal cavity. In another[12] the recurrence occurred at the site of specimen retrieval with possible trauma to the specimen at the time of extraction[12].

The presence of port-site recurrence may have little bearing on the final outcome of patients with advanced disease. While often painful, their development may be an acceptable price to pay for accurate staging and avoidance of a laparotomy.

Radical lymphadenectomy in the management of early gastric cancer

N. HAYES, D. KARAT, D. J. SCOTT*, S. A. RAIMES and S. M. GRIFFIN

*Oesophago-Gastric Cancer Unit and *Institute of Pathology, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE, UK*
Correspondence to: Mr S. M. Griffin

Lymph node metastasis in patients with early gastric cancer was evaluated prospectively to determine whether radical (D_2) lymphadenectomy is appropriate in such cases. Twenty-eight (18 per cent) of 156 patients having surgery for gastric cancer had early disease. Lymph node metastasis was found in 12 of the 28 patients. Metastasis was more likely in submucosal than mucosal early gastric cancer (nine of 14 *versus* three of 14; $P = 0{\cdot}024$, Fisher's exact test). In two of three patients with metastasis at the N_2 level, the N_1 nodes were entirely clear. This study shows a higher incidence of lymph node metastasis than has been reported previously in both the UK and Japan. The high incidence of lymph node metastasis in early gastric cancer supports the continuing use of radical lymphadenectomy in patients who are fit for such major surgery.

Traditionally, patients in the UK with gastric cancer have been perceived to have a poor prognosis. Survival in an individual case is best predicted by the clinicopathological stage of the tumour, and in recent years there has been an increase in the proportion of patients presenting with earlier stage disease[1,2]. It has now been shown that such patients can be treated with the expectation of survival rates to equal the exceptional results hitherto obtained only in Japanese centres[3]. In 1962 the Japanese Endoscopic Society defined early gastric cancer as that in which the depth of tumour invasion is limited to the submucosal layer at worst[4]. This diagnosis has become synonymous with cancer that is amenable to surgical cure, but the debate on what constitutes the optimum surgical management for early gastric cancer has not been concluded.

Some authors have suggested that early gastric cancer can be treated adequately by less aggressive surgery[5] and, furthermore, some Japanese units advocate local endoscopic surgery alone for selected patients with mucosal early gastric cancer[6,7]. Other authorities advocate radical gastrectomy with *en bloc* lymphadenectomy for all patients with gastric cancer in whom cure is a possibility[1,8,9]. The purpose of this study was prospectively to record the lymph node status of patients with early gastric cancer to determine whether an aggressive surgical approach to gastric cancer as a whole is justifiably applied to earlier stage disease.

Patients and methods

This study took place over a period of 48 months from April 1990, and all consecutive patients undergoing surgical exploration for biopsy-proven adenocarcinoma of the stomach were included. Before operation patients were investigated for metastatic disease by abdominal ultrasonography and spiral computed tomography. At laparotomy the surgeon evaluated the disease stage according to guidelines from the Japanese Research Society for Stomach Cancer[10]. It was the policy of this unit for patients to undergo gastrectomy with radical (D_2) lymphadenectomy; however, patients unfit for such major surgery because of coincidental medical conditions underwent a standard resection (D_1). Patients with disseminated peritoneal or hepatic metastases (M_1) underwent palliative surgery only.

Gastrectomy specimens were immediately transferred to the pathology department where the lymph-bearing adnexae were dissected from the stomach and fixed separately in groups or node 'stations' recorded according to Japanese guidelines[10] The stomach was opened while fresh along the greater curvature and pinned to a cork board before fixation. Tumour morphology was recorded with the Borrmann classification for advanced cancers[11] and Murakami's method for early gastric cancer[4]. Lymph nodes were individually dissected from the surrounding fatty tissue after fixation in formaldehyde solution, and histological assessment of each gland was performed in three sections if the 'equatorial' section was negative. The depth of invasion of the primary cancer was examined meticulously, and tumours involving the mucosal or submucosal planes only, irrespective of lymph node status, were categorized as early gastric cancer.

Postoperative complications and deaths were recorded for the period covering 30 days after surgery, or for the hospital stay if it exceeded 30 days.

Results

During the study period 156 patients underwent surgical evaluation with a view to gastrectomy. Twenty-eight patients (18 per cent) (19 men and nine women aged 54–82 years) had early gastric cancer and are discussed further below.

Fifteen patients had a D_1 gastrectomy and the remainder had a D_2 resection. The median (range) number of lymph nodes recovered was 16 (6–25) for D_1 and 20 (10–53) for D_2. Two patients with D_1 resections had a completion gastrectomy for stump cancer after previous surgery for peptic ulcer. *Table 1* shows how the operations were stratified.

Nine patients had positive nodes retrieved from the N_1 tier, one had positive nodes at N_1 and N_2 sites, and two had positive lymph nodes at the N_2 level only. Two patients with early gastric cancer had protruding (type I) tumours; both were node negative. Twenty patients had superficial cancer (type II) and six had excavated or combined cancers (types III or II–III) but the early gastric cancer morphology had no bearing on node status.

Table 1 Lymphadenectomies performed stratified by operation

	D_1	D_2	Total
Total gastrectomy	5	7	12
Subtotal gastrectomy	8	6	14
Completion gastrectomy	2	0	2

Table 2 Node status in early gastric cancer according to depth of tumour

Depth of invasion	N_0	N_1	N_2	Total
Mucosa	11	2	1	14
Submucosa*	5	7	2	14
Total	16	9	3	28

*Submucosal cancer had a significantly higher proportion of node-positive cases ($P = 0{\cdot}024$, Fisher's exact test)

However, metastasis to lymph nodes was significantly more likely if the primary tumour had penetrated into the submucosal layer (nine of 14 patients *versus* three of 14 with mucosal cancer; $P = 0{\cdot}024$, Fisher's exact test). *Table 2* shows the nodal status according to depth of tumour.

The 28 operations were performed with no deaths, but complications occurred in two patients. A 58-year-old man had undergone D_2 total gastrectomy and required emergency laparotomy on the 11th postoperative day for secondary haemorrhage from the right gastric artery stump. The second complication was in a 55-year-old man who had a D_2 total gastrectomy and developed a duodenal stump leak on the seventh postoperative day, which closed spontaneously after conservative management. Only limited follow-up data are available for the patients to date, but there have been no deaths from recurrent adenocarcinoma.

Discussion

In this series 12 of 28 patients with early gastric cancer had lymph node metastasis. This includes nine of 14 patients with submucosal cancer, and three of 14 with cancer confined to the mucosal layer. These results contrast sharply with those from either Japan or the West, where lymph node metastases have been found in up to 20 per cent of patients with submucosal cancer and in up to 5 per cent of those with mucosal cancer[3,6,8,12].

There are some factors that suggest that this already high incidence of lymph node metastasis in early gastric carcinoma may be an underestimate. In two of the three cases where nodes in the second tier (N_2) were found to be positive, the first tier nodes were all negative, demonstrating that node 'skipping' can occur. Fifteen of the present patients were considered fit enough for only D_1 lymphadenectomy, and as the N_2 nodes were not sampled in this group there is a potential for understaging. In this study the number of lymph nodes retrieved appears to be lower than that quoted for similar operations in Japanese reports[13,14]. The lymph node retrieval method used involves the dissection of fatty tissue at the node stations after fixation. It is possible that by immediate bench dissection of the fresh specimen, as practised in many Japanese operating departments (T. Sano, personal communication), or by chemical lipid clearance, as described by Wagner and colleagues[15] in Marburg, a greater number of nodes might have been obtained. The limitations of lymph node retrieval make the present findings all the more remarkable.

To explain the difference between the present results and those usually found in the literature, it may be suggested that the primary lesion was understaged. However, the majority of early gastric cancers were less than 4 cm in diameter, and the pathology service routinely takes 5-mm blocks from the entire cancer. Sections are examined from each block, leading to a thorough survey of the vital submucosal–muscularis propria interface across the whole tumour[16]. Hence, the depth of tumour penetration was assessed as meticulously in these specimens as in those from reports published elsewhere.

Second, the Japanese rules on lymph node examination appear to be open to some interpretation; there seems to be a variety of recommended methods of nodal examination, from serial sectioning of all nodes to representative examination of one node per group or station[10]. A meticulous three-section examination of every resected node was chosen for the present study, which probably increased the detection of so-called 'micrometastases'. Such tiny tumour emboli are found in the peripheral sinusoids of the nodes and can be easily overlooked. Gunvén and colleagues[17] have shown that such micrometastases do not necessarily worsen prognosis, as they result in disease upstaging. Far from supporting a reduction in lymph node surveillance, this work encourages attention to detail in order to understand the metastatic process further.

The results of this study suggest that the conservative methods of treatment for early gastric cancer developed by the Japanese[6] are not appropriate in the UK. If a nihilistic approach toward the treatment of early gastric cancer is taken, as has been advocated in the West[5,18], the chance of cure would be denied to a significant proportion of patients. On the basis of this study it is suggested that the role of extended lymphadenectomy in early gastric cancer is proven. Preoperative and operative disease staging is still an inexact science, and the depth of tumour penetration or lymph node status in individual cases cannot yet be decided with certainty before histological confirmation. Preoperative staging of gastric cancer with the use of endoluminal ultrasound probes is being evaluated currently[19], and may eventually be routine. However, at present, the surgeon cannot with any certainty know the stage of a gastric cancer at operation. Radical gastrectomy with extended lymphadenectomy can be performed with an acceptable morbidity and low mortality rate in fit patients and is the treatment of choice in early gastric cancer. Far from suggesting a less aggressive approach for this disease, it is precisely these patients, in whom surgical cure is a realistic goal, who deserve the most radical procedures.

Accuracy of laparoscopic ultrasonography in the staging of upper gastrointestinal malignancy

D. N. ANDERSON, S. CAMPBELL* and K. G. M. PARK

*Departments of Surgery and *Radiology, Aberdeen Royal Infirmary, Foresterhill, Aberdeen AB9 2ZB, UK*
Correspondence to. Mr K. G M. Park

Laparoscopic ultrasonographic staging was compared prospectively with conventional computed tomography (CT) and ultrasonographic staging of 24 lower-third oesophageal tumours and 20 gastric malignancies. Following laparoscopic ultrasonography, seven patients regarded as being resectable after conventional imaging were excluded from surgical exploration because of ascites with peritoneal deposits (four patients), liver metastases (one), advanced local disease (one) and poor tolerance of general anaesthesia (one). Preoperative T and N stages were compared with the pathological staging following resection in 34 patients. Laparoscopic ultrasonography was significantly more accurate than conventional CT and ultrasonography in assessment of the primary tumour (91 *versus* 64 per cent, $P<0{\cdot}01$) and nodal status (91 *versus* 62 per cent, $P<0{\cdot}05$). The addition of laparoscopic ultrasonography to conventional procedures for staging upper gastrointestinal malignancy improved the overall accuracy of staging. Although this may have future implications for the selection of patients for multimodality treatment, management decisions are currently based on laparoscopic findings, which in this study resulted in a resection rate of 97 per cent.

Accurate staging of upper gastrointestinal malignancy is essential if patients are to receive optimal treatment and to ensure maximal use of resources. Unfortunately conventional imaging with ultrasonography and computed tomography (CT) is not always accurate in the staging of patients with gastro-oesophageal cancer[1–4]. Many studies[5–9] report a high incidence of tumours that are found to be irresectable at the time of surgery. These patients may have been more appropriately treated with non-operative palliative measures, which in many cases can provide a good quality of life[10–12]. A recent report[13] has highlighted the benefits of laparoscopic evaluation of patients with gastro-oesophageal cancer; however, laparoscopy alone does not allow a full evaluation of the tumour without trial dissection, which may compromise the feasibility of a future *en bloc* resection. The combination of laparoscopy and ultrasonography may give additional benefits as it allows direct contact between the ultrasonographic probe and the organ of interest, enabling the use of high-frequency ultrasound with high resolution[14]. Previous authors[15,16] have reported the use of laparoscopic ultrasonography in the evaluation of pancreatic tumours and the biliary tree. Results of laparoscopic ultrasonography in the staging of patients with upper gastrointestinal cancer are reported and compared with those of more conventional staging modalities, to determine the accuracy of laparoscopic ultrasonography in staging upper gastrointestinal cancer.

Patients and methods

Patients

Between January and November 1995, 44 patients with a diagnosis of lower-third oesophageal cancer or gastric malignancy were staged according to a standard protocol This involved full blood count, liver function tests, chest radiography, endoscopy (and biopsy) of the upper gastrointestinal tract, abdominal ultrasonography and dynamic contrast-enhanced CT of the chest, mediastinum and upper abdomen. The CT protocol involved contiguous 10-mm collimated sections from the sternal notch to the inferior border of the liver. Intravenous contrast was commenced at the level of the tracheal bifurcation, using 100 ml iopamidol 370 (Merck Pharmaceuticals, West Drayton, UK): 40 ml at 2 ml/s and 60 ml at 0·5 ml/s. Oral contrast, 300 ml 2 per cent Gastrografin (Schering Health Care, Burgess Hill, UK), was administered before the examination. The results of the staging investigations were reviewed by one consultant radiologist (S.C.) and the consultant surgeon in charge of the case (K.G.M.P.) and the details were recorded prospectively. Thereafter each patient was examined with laparoscopic ultrasonography and the staging was modified accordingly. The final diagnosis in each patient is shown in *Table 1*.

Laparoscopic ultrasonography

Laparoscopic ultrasonography was performed as a separate procedure under general anaesthesia. Both surgeons involved were experienced endoscopic surgeons but had little experience of ultrasonography and therefore the images were interpreted by a consultant radiologist (S.C.), who had considerable experience in gastrointestinal and endoscopic ultrasonography and was

present at each operation. An Aloka (Tokyo, Japan) 7·5-MHz rigid linear array probe was used in all patients. A 10-mm cannula was inserted at the umbilicus using a blunt technique and a pneumoperitoneum was induced with carbon dioxide A 0° laparoscope was then inserted and the peritoneum was inspected. Further 10-mm cannulas were inserted in the right and left sides of the abdomen to allow insertion of the ultrasonographic probe and grasping forceps or suction irrigation probes Any free fluid was aspirated for cytological analysis and peritoneal deposits were biopsied. Using the forceps in the right port, the liver was retracted in a cephalad direction and the anterior surface of the stomach was inspected. The ultrasonographic probe was then inserted through the left port and used to scan the stomach, liver and biliary tree.

The probe was moved to the right port and again the liver and porta hepatis were examined. Care was taken to scan both lobes of the liver and to identify the right and left hepatic veins and the portal confluence. Unless these anatomical landmarks were identified the examination was noted as incomplete. Abnormalities seen within the liver were biopsied if there was suspicion of malignancy. The probe was then brought back across the stomach and lesser curve, the aorta was visualized with any anterior lymphadenopathy and the coeliac axis was inspected. Care was taken to identify the left gastric artery. The probe was inserted into the lesser sac through the lesser omentum, to allow inspection of the posterior surface of the stomach and also to assess the degree of fixation of the tumour.

Nodes greater than 8 mm in maximum diameter were generally regarded as being positive for metastatic tumour. Other ultrasonographic features used to diagnose nodal metastasis were the loss of the normal internal hyperechogenicity and loss of the normal oval shape of lymph nodes Involved nodes tended to be rounder in appearance. When examining the primary tumour, initial laparoscopic inspection identified serosal involvement. Laparoscopic imaging was used to identify the five ultrasonographic layers of the bowel wall described previously[17], to assess earlier tumours.

At the end of the examination the pneumoperitoneum was released through the trocars before their removal.

Laparotomy

Surgical exploration was carried out within 3 weeks of completion of staging investigations. At this time the extent of the local tumour was determined and the degree of fixation to adjacent organs was assessed. The liver and the peritoneal cavity were carefully inspected and palpated. Final staging was according to the Union Internacional Contra la Cancrum tumour node metastasis (TNM) system[18].

Invasion through the wall of the stomach or oesophagus was determined on the resected pathological specimen. Lymph nodes from each compartment were also dissected from the specimen for separate histological analysis These findings were correlated with the results of conventional staging and laparoscopic ultrasonography.

Statistical analysis

The accuracy of laparoscopic ultrasonography and conventional staging in the assessment of the primary tumour, lymph nodes and hepatic metastases was determined and compared with the pathological staging using a paired McNemar's χ^2 test.

Results

Laparoscopy was performed in all patients but inspection was incomplete in five because of the presence of adhesions from previous surgery. Median operating time was 30 (range 15–65) min and there was one minor complication of port-site haematoma, which did not require any treatment. Patients were allowed to eat after recovery from the anaesthetic and all were fully ambulant on the evening of the procedure.

Resection

Nine patients did not undergo resection following laparoscopic ultrasonography. In five patients this was because of advanced disease: four patients had malignant ascites with peritoneal metastases, one of whom also had hepatic metastases, and one further patient had liver metastases that were not detected with conventional imaging techniques. One elderly man was found to have a more locally advanced tumour than was apparent on CT and it was decided not to proceed to thoracolaparotomy. One other patient tolerated a pneumoperitoneum and general anaesthetic so poorly that it was judged unwise to proceed to a major operation despite the tumour being potentially resectable. Two patients are currently receiving neoadjuvant chemotherapy within a controlled trial and will be further evaluated before resection. Thirty-five patients have undergone surgery with the aim of resection and this has been achieved in 34; there was one death within 30 days. In 30 patients there was no evidence of macroscopic or microscopic tumour after resection (R_0), in three there was microscopic evidence of tumour at the resection margins (R_1) and in one patient there were macroscopic peritoneal deposits remaining after resection (R_2).

The only patient found to have an irresectable tumour underwent thoracoabdominal exploration for delayed gastric emptying 18 months after oesophageal resection for adenocarcinoma. Preoperative staging and laparoscopic ultrasonography had shown no evidence of recurrent tumour but at the time of surgery large tumour plaques were identified in the right pleural cavity and adherent to the intrathoracic stomach. The patient who died had a more extensive intrathoracic tumour than had been apparent before operation. Transhiatal oesophagectomy resulted in heavy blood loss at the time of the procedure and the patient suffered a myocardial infarction and cardiac arrest in the postoperative period.

Pathological correlation

Primary tumour. In 14 patients with resected lower-third oesophageal cancer laparoscopic ultrasonography was used to assess extension of the primary tumour into the stomach and around the hiatus. Involvement of the fundus of the stomach was confirmed histologically in two of 14 patients. CT detected this in one patient; in addition there was one false-positive CT result. Laparoscopic ultrasonography detected fundal involvement in one patient and was unable to visualize the fundus adequately in the other patient because of a large hiatus hernia.

Table 2 shows a comparison of the accuracy of laparoscopic ultrasonography and conventional staging for the T stage of the 22 patients with resected tumours involving the stomach. There were five patients in whom endoscopy and biopsy suggested early gastric cancer; in none of these was the primary lesion visualized on CT and all were regarded as having early gastric cancer. In only one was this confirmed histologically in the resected specimen. Laparoscopic ultrasonography was unable to visualize the true case of early gastric cancer but in the other four suspected cases it revealed more extensive invasion through the stomach wall.

In one patient there was direct invasion of a tumour into the liver, pancreas and transverse colon; this was clear at laparoscopy and laparoscopic ultrasonography but was not apparent on CT. There were two patients in

Table 2 Accuracy of laparoscopic ultrasonography and conventional staging investigations in the assessment of primary tumour stage in lesions involving the stomach

Primary lesion	Histology	Laparoscopic ultrasonography	Conventional staging*
Limited to gastric wall ($T_{1,2}$)	4	2	3
Invades serosa (T_3)	16	16	10
Invades adjacent organs (T_4)	2	2	1
Accuracy	0	20 of 22 (91)	14 of 22 (64)
No. overstaged	0	2	4
No. understaged	0	0	4

Values in parentheses are percentages. *Includes endoscopy (plus biopsy), ultrasonography and computed tomography. Only the number of correct investigations is shown for laparoscopic ultrasonography and conventional staging

whom CT suggested extensive invasion around the hiatus with involvement of the aorta; this was not confirmed on laparoscopic ultrasonography or at laparotomy. Of the 22 primary tumours that could be visualized with laparoscopic ultrasonography, staging was correct in 20 compared with 14 for conventional investigations ($P<0.01$).

Intra-abdominal lymph nodes. Histology of the 34 resected specimens showed involvement of intra-abdominal lymph nodes in 18 cases. Laparoscopic ultrasonography correctly identified 16 whereas CT demonstrated only five of these. There was one false-positive result with laparoscopic ultrasonography and no false positives with CT. This gives a positive predictive value of 94 per cent for laparoscopic ultrasonography and 100 per cent for CT. There were two false negatives with laparoscopic ultrasonography, in one patient resulting from a large hiatus hernia with nodes along the lesser curvature which could not be well seen and in a second from a combination of obesity and previous surgery which limited the view. The negative predictive value of laparoscopic ultrasonography was 88 per cent compared with 52 per cent for CT. *Table 3* compares the accuracy of laparoscopic ultrasonography and CT for the assessment of intra-abdominal lymph nodes. The accuracy of CT was 62 per cent and that of laparoscopic ultrasonography was 91 per cent ($P<0.05$).

Hepatic metastases. Inspection of the liver was incomplete in five patients because of the presence of adhesions from previous surgery. In the remaining patients the presence of liver metastases suspected on CT or ultrasonography was confirmed in two patients. In one of these patients, however, it was not possible to visualize a metastasis in segment VIII, identified on CT, as it proved impossible to manipulate the rigid probe into a suitable position. In one other patient a 7-mm metastasis was seen on laparoscopic ultrasonography but was not visualized with other staging modalities. In each case laparoscopic guided biopsy was used to confirm the presence of liver metastases. Two patients were thought to have liver metastases on CT and conventional ultrasonography but on laparoscopic ultrasonography were found to have benign pathology (liver cysts and a haemangioma).

Table 3 Comparison of laparoscopic ultrasonography and computed tomography in the assessment of intra-abdominal lymph nodes in patients with upper gastrointestinal cancer

	Histology	
	Positive	Negative
Computed tomography		
Positive	5	0
Negative	13	16
Laparoscopic ultrasonography		
Positive	16	1
Negative	2	15

Intraperitoneal metastases. In four patients the presence of ascites was demonstrated on laparoscopy; this had been suggested in one patient by CT or ultrasonography. In addition, peritoneal deposits were demonstrated in the pelvis of one patient who had received preoperative chemotherapy with demonstrable shrinkage of a primary gastric tumour that had previously been fixed to the pancreas. However, both laparoscopic ultrasonography and conventional imaging failed to demonstrate the presence of tumour studs in the lesser sac, which were evident at the time of resection.

Miscellaneous lesions. One patient had a large tumour of the ascending colon visualized on both CT and barium enema examination, in addition to the gastric cancer. Despite careful inspection at laparoscopy and laparoscopic ultrasonography it was not possible to demonstrate what subsequently turned out to be a large colonic tumour. In one other patient laparoscopic ultrasonography demonstrated a mucocele of the gallbladder that was not visualized on CT or conventional ultrasonography.

Discussion

The value of laparoscopic evaluation of upper gastrointestinal cancer has been demonstrated previously[13]. Furthermore, in hepatobiliary tumours the addition of high-frequency high-resolution ultrasonography to laparoscopy has led to better staging and patient selection for resectional surgery[15,16]. In this series the addition of laparoscopic ultrasonography to conventional imaging resulted in seven of 43 patients who would have been regarded as having resectable disease, by ultrasonography and CT, being excluded from operation. This was because of peritoneal deposits (four patients), liver metastases (one) and extensive local disease (one). In addition, one patient was excluded after poor tolerance of a general anaesthetic. The exclusion of these patients resulted in a resection rate of 97 per cent (34 of 35 patients) with one perioperative death. This is in contrast to a 79 per cent resection rate if all patients thought to have resectable disease after conventional staging had proceeded to laparotomy. In each of these patients the presence of advanced disease was identified on laparoscopy alone; no further patient was excluded from surgical exploration on the basis of laparoscopic ultrasonography. However, laparoscopy alone is poor at demonstrating the presence of lymph node metastases and the stage of the primary tumour[13,19]. In this series a combination of endoscopy, CT and transabdominal ultrasonography correctly staged 64 per cent of the primary tumours in patients with gastric malignancy or lower-third oesophageal tumours extending into the gastric fundus. Similar results for CT have been found in other centres[1–4]. Laparoscopy and laparoscopic ultrasonography improved the accuracy of T staging in these patients to 91 per cent. Similarly, the accuracy of CT in identifying positive intra-abdominal lymph nodes was 62 per cent compared with 91 per cent for laparoscopic ultrasonography. Although it is clear that the addition of laparoscopic ultrasonography significantly improved T and N staging of patients with gastro-oesophageal tumours, at present this contributes little to the management of these patients. It has been proposed, however, that neoadjuvant chemotherapy should be targeted to patients with stage III and IV disease[20]. To date conventional imaging has made preoperative assessment of patients for neoadjuvant chemotherapy unreliable. However, laparoscopic ultrasonography may allow improved patient selection for such treatment.

There were two patients in whom the combination of laparoscopic ultrasonography and conventional staging failed to identify the advanced nature of intrathoracic tumours; in one patient the tumour was not resected and in the other there was a more extensive dissection than was envisaged and this led to the only perioperative death. Perhaps the combination of laparoscopic and endoscopic ultrasonography would allow more thorough assessment of both intra-abdominal and intrathoracic disease in patients with such tumours[21,22].

In the present series laparoscopic ultrasonography required an additional general anaesthetic and a median of 30 min of operating time. As previous studies have found, this procedure was associated with minimal morbidity[13,15,20,23]; however, it does subject the patient to the potential risk of port-site implantation of tumour cells. A number of reports have now described the occurrence of tumour recurrence at laparoscopy port sites[24–26]. In a recent UK postal survey of laparoscopy in intra-abdominal cancer, port-site recurrence was identified in 4 per cent of patients. This was most common in colorectal excisions (12 per cent) and lowest in diagnostic laparoscopy[27]. Similarly, other groups have reported port-site metastases to be most common in the presence of exfoliated cells, i.e. in malignant ascites or where there has been tumour mobilization[24,25]. The addition of ultrasonography to laparoscopy may reduce the potential for port-site implantation compared with other laparoscopic techniques, as less tumour manipulation and minimal dissection are required to obtain adequate staging.

In conclusion, laparoscopic ultrasonography of patients with gastro-oesophageal cancer resulted in accurate staging of these patients. This may allow better selection of patients for multimodality treatments in the future. In the present series, the addition of laparoscopic ultrasonography to conventional imaging techniques resulted in better selection of patients for resectional surgery and a resection rate of 97 per cent.

Oesophagogastrectomy for iatrogenic perforation of oesophageal and cardia carcinoma

D. J. ADAM, A. M. THOMPSON*, W. S. WALKER and E. W. J. CAMERON

*Department of Thoracic Surgery, City Hospital and *Department of Surgery, Western General Hospital, Edinburgh, UK*
Correspondence to Mr D. J. Adam, Department of Vascular Surgery, Royal Infirmary of Edinburgh, Lauriston Place, Edinburgh EH3 9YW, UK

A casenote review identified 18 patients with carcinoma of the oesophagus and gastric cardia who underwent transthoracic oesophagectomy after instrumental perforation. Oesophagectomy was performed within 48 h in ten patients (early surgery group) and after a median delay of 22 (range 5–48) days in eight patients (delayed surgery group). All patients underwent resection via left thoracolaparotomy with immediate intrathoracic anastomosis using the stomach in 17 of 18 patients. There were no anastomotic leaks. Significant postoperative complications occurred in five of ten of the early group with two in-hospital deaths and a mean survival of 551 days. Six of eight patients in the delayed group developed postoperative complications with two in-hospital deaths and a mean survival of 297 days. Transthoracic resection with immediate intrathoracic anastomosis can be performed without anastomotic leakage but there is high associated respiratory morbidity. The timing of oesophagectomy has little effect on hospital morbidity or mortality rates but early surgery is associated with better long-term survival.

The mortality rate for iatrogenic oesophageal perforation associated with carcinoma is more than twice that for benign disease[1] and higher than that for normal oesophagus[2]. In such circumstances, oesophagectomy offers the only hope of survival and cure as the perforation is unlikely to heal with conservative management[3] or simple repair[4]. Most surgeons perform oesophagectomy within 24 h as delay beyond this is said to be associated with higher morbidity and mortality rates[2,5,6]. However, the best method of oesophagectomy (transhiatal or transthoracic), the extent of resection and site of anastomosis (intrathoracic[7–9] or cervical[4,10]) and the optimal time to restore intestinal continuity, whether immediate[4,7,8,10,11] or delayed[4,5,12,13], continue to stimulate debate.

A retrospective study was undertaken to audit the authors' experience over the previous decade to determine future policy in terms of operative approach and timing of surgery. This series represents, to their knowledge, the largest reported experience of resectional therapy for perforated carcinoma of the oesophagus and gastric cardia from a single surgical unit.

Patients and methods

Over the 10-year period from January 1983 to December 1992, 597 patients underwent resection for carcinoma of the oesophagus or gastric cardia in the Thoracic Surgical Unit, City Hospital, Edinburgh. During this time, 18 patients (3 per cent) underwent oesophagectomy with immediate reconstruction following instrumental perforation of the thoracic oesophagus. Six patients sustained perforation in another unit and were transferred for resection. Perforation was due to attempted dilatation of a malignant stricture in 12 of the 18 patients, attempted pulsion intubation in three and diagnostic rigid oesophagoscopy and biopsy in three. Perforations that were not diagnosed immediately were located radiologically by contrast swallow. All perforations occurred just proximal to or within the area of the carcinoma.

Among the ten women and eight men, the median age was 65 (range 48–83) years and ten patients had significant pre-existing cardiorespiratory disease (*Table 1*). No patient had received preoperative radiotherapy or chemotherapy.

Ten patients (early surgery group) underwent oesophagectomy within 48 h of perforation, nine of whom underwent operation within 24 h. Perforation was diagnosed immediately in three patients who proceeded to surgery without delay. The diagnosis was delayed in the remaining patients; the mean interval from perforation to surgery was 10 h for the nine patients who underwent oesophagectomy within 24 h.

Eight patients were managed conservatively with gastrointestinal rest, intravenous fluid and antibiotic therapy and closed tube thoracostomy (delayed surgery group) for 5, 6, 19, 21, 23, 26, 26 and 48 (median 22) days before surgery. All patients had their perforations diagnosed on the day of perforation. Four patients were diagnosed and managed in other units and transferred for resection once their clinical status had improved.

Results

Pathology

Squamous cell carcinoma was present in ten patients and adenocarcinoma in eight. Local lymph node metastases (N_1) were present in seven patients with distant nodes (N_2) involved in two. Tumours were staged by the American Joint Committee on Cancer guidelines[14]; stage IIA, IIB, III and IV disease was present in seven, one, eight and two patients respectively. One patient who underwent total oesophagectomy with cervical anastomosis for a tumour in the proximal third of the oesophagus had pathological evidence of residual tumour at the margins of resection.

Surgical technique

All patients underwent resection via single-stage left thoracolaparotomy. One patient required additional right thoracotomy and pneumonectomy to resect an oesophageal lesion invading the right main bronchus and a synchronous squamous carcinoma of the right lower lobe of the lung. The thoracic oesophagus including the perforated portion was mobilized to at least 5 cm above

IHD, ischaemic heart disease; COAD, chronic obstructive airways disease; CVA, cerebrovascular accident; NIDDM, non-insulin-dependent diabetes mellitus; MI, myocardial infarction; AF, atrial fibrillation; MVR, mitral valve replacement; IPPV, intermittent positive pressure ventilation; TPN, total parenteral nutrition

the upper limit of the tumour, taking regional lymph nodes and contents of both pulmonary ligaments *en bloc*. The stomach was mobilized by division of the short gastric vessels, then distally outwith the gastroepiploic arcade preserving omentum for an anastomotic wrap. The left gastric vessels were divided at the upper border of the pancreas and all associated coeliac and left gastric pedicle lymph nodes were taken with the operative specimen. No patient required wedge resection of liver or lung or splenectomy or partial pancreatectomy to achieve macroscopic tumour clearance. The pylorus was dilated digitally or with Hegar's dilators. Stomach was used to restore intestinal continuity in all cases. One patient with squamous carcinoma of the upper third of the oesophagus underwent total oesophagectomy with cervical anastomosis. Subtotal oesophagectomy with anastomosis at or above the aortic arch was performed in 14 patients with five middle-third and nine distal-third lesions. Oesophagogastrectomy was performed in three patients for one distal-third oesophagus and two cardia lesions. The anastomosis was performed with either a single-layer (ten patients) or two-layer (three) handsewn technique, or with a stapling device in five patients.

Mean operative blood loss was 410 (range 100–1250) ml for those undergoing surgery within 48 h and 1088 (range 200–2650) ml for those in the delayed group. Mean transfusion requirement was 495 (range 0–2400) ml for the early group compared with 1629 (range 0–3950) ml in the delayed group.

Complications and survival

None of the 18 patients had clinical or radiological evidence of anastomotic leakage. Five patients in the early surgery group and two in the delayed surgery group had no postoperative complications. However, the incidence of respiratory complications was high with seven of 18 patients requiring ventilatory support (mean 9 (range 4–21) days), of whom five required tracheostomy and four died. Tracheostomy was performed in another three patients to allow bronchial toilet without ventilation. Five patients required inotropic support and four received total parenteral nutrition. Chylothorax occurred in two patients: one of these was managed conservatively and the other underwent repeat thoracotomy but both patients died after 17 and 21 days respectively. Median in-patient stay was 16 (range 6–42) days. The overall in-hospital mortality rate was 22 per cent (four of 18 patients).

All 14 survivors were able to swallow on discharge home, and ten had no further dysphagia. One patient required four dilatations for benign stricture. Three patients underwent dilatation for recurrent disease and two proceeded to pulsion intubation. No patient was given postoperative adjuvant therapy.

Among the ten patients who underwent early surgery there were two in-hospital deaths. Two patients died from recurrent disease and one from an unknown cause within the first year. Two died from recurrent disease within the second year. Three patients who were resected for stage IIA disease are still alive with no evidence of disease recurrence at 24, 49 and 58 months after surgery. The mean survival for the group is 551 (range 17–1780) days.

There were two in-patient deaths in the eight patients who had surgery delayed for more than 48 h. Two patients died within the first year, one from recurrent disease and the other after admission to another hospital with an acute abdomen. Four died within the second year after surgery, three with recurrence and one from an unknown cause. Mean survival for this group was 297 (range 21–546) days.

Discussion

Oesophagectomy for iatrogenic perforated carcinoma is uncommon, accounting for only 3 per cent of all resections for carcinoma in this unit.

Even in a contaminated operative field, it was possible to perform immediate intrathoracic oesophagogastrostomy, as used in the majority of elective resections in this unit, without anastomotic leakage. Palliation of symptoms was excellent with all 14 survivors discharged home and able to swallow. Two of 18 patients are alive and free from disease over 4 years after surgery: comparable with the authors' overall 5-year survival rate of 16 per cent for all resected patients and with other publications reporting long-term survival[8,10,11,15]. Left thoracolaparotomy with intrathoracic anastomosis does not result in an increased incidence of anastomotic leakage or provide poor tumour clearance[10]. Only one patient, with carcinoma of the proximal oesophagus, had residual tumour at the margins of resection despite undergoing total thoracic oesophagectomy with a cervical anastomosis. None of the five patients with mid-oesophageal tumours had an incomplete resection. More extensive mobilization and resection, for example by transhiatal[4] or thoracoabdominal approach[10] with immediate cervical anastomosis, does not provide better operative exposure and would have little prospect of providing better palliation or long-term survival. Furthermore, although oesophageal exclusion and two-stage reconstruction is a useful technique in certain circumstances, for perforated carcinoma[4] it provides poor palliation of symptoms compared with immediate reconstruction.

In this series, early resection with two-field lymphadenectomy was associated with less operative blood loss and a lower transfusion requirement than delayed resection or transhiatal oesophagectomy without lymphadenectomy for perforations of benign disease[4]. Postoperative morbidity was high: five of ten undergoing early oesophagectomy and six of eight undergoing delayed resection experienced significant complications. Respiratory complications were particularly common and probably related to acute intrathoracic pathology and thoracotomy in the presence of co-existing cardiorespiratory disease and carcinoma. While early transhiatal oesophagectomy may be associated with a lower incidence of postoperative complications for perforations of benign disease[4], the mortality rate in the present series compares favourably with that reported elsewhere for benign[4,16–18] or malignant[2,10,19–21] disease regardless of surgical approach. The 30-day mortality rate associated with early or delayed surgery was similar and suggests that the timing of oesophagectomy may not be important for survival of the acute episode, although why early surgery should confer a long-term survival advantage remains uncertain.

The present study describes, to the authors' knowledge, the largest reported series of resections performed for perforated oesophageal and cardia carcinoma in a single surgical unit. Despite this, the number of patients studied is too small to make valid statistical conclusions. However, this study has demonstrated that transthoracic oesophagectomy with immediate intrathoracic anastomosis can be performed with low blood loss and without anastomotic dehiscence. Although associated respiratory morbidity is high, the mortality rate is comparable to that for transhiatal or transthoracic oesophagectomy with cervical anastomosis, and the procedure gives excellent palliation of symptoms with the prospect of long-term survival comparable to that for uncomplicated cases of carcinoma. The same surgical technique can be used for perforated carcinoma as for elective resection. There is no place for postponing surgery or delayed reconstruction which provides poor palliation.

Proximal pancreatoduodenectomy for chronic pancreatitis

G. N. STAPLETON and R. C. N. WILLIAMSON

Department of Surgery, Hammersmith Hospital and Royal Postgraduate Medical School, Du Cane Road, London W12 0NN, UK
Correspondence to Professor R. C N. Williamson

A personal series is reported of 52 patients who underwent proximal pancreatoduodenectomy for severe chronic pancreatitis between 1979 and 1994. There were 13 women and 39 men of median age 42·2 (range 12–70) years. Disease predominantly affected the head of pancreas, with calcification present in 37 patients. Indications for operation were chronic pain (47 patients), obstructive jaundice (19) and duodenal stenosis (six); cancer was suspected in 12. In addition, 14 patients had a pseudocyst, two pancreatic endocrine failure and 20 exocrine failure. Aetiology was chronic alcohol abuse in 34, recurrent acute pancreatitis in five and unknown in 13. Pylorus-preserving proximal pancreatoduodenectomy was performed in 45 patients, while the remaining seven had partial gastrectomy. Drainage of a dilated distal pancreatic duct by side-to-side pancreaticojejunal anastomosis was included in 15 patients. Mean operating time was 6·2 (range 4·5–9·5) h and mean blood loss was 2·7 (range 0·2–13·0) litres. There were no hospital deaths, but three patients required a second operation and five had percutaneous drainage of infected collections. During a median follow-up of 54 months, six patients required completion distal pancreatectomy for renewed pain and four others had persistent pain. Four patients required intervention for stricture at the biliary–enteric anastomosis. Ten patients have died from causes not directly related to chronic pancreatitis. Proximal pancreatoduodenectomy is a relatively safe procedure, effectively palliating pain in 80 per cent of patients with chronic pancreatitis.

Management of intractable pain is the greatest challenge posed by chronic pancreatitis. Increasing doses of narcotics add the problem of drug dependency to a group of patients many of whom are already addicted to alcohol. Although the pathogenesis of the pain is poorly understood, control measures are based on the premise of hypertension in the pancreatic duct and parenchyma or inflammatory neuritis in the pancreas itself and surrounding tissues. The ideal interventional procedure would provide long-term analgesia with minimal operative risk and without aggravating pancreatic dysfunction, but this ideal is elusive.

Pain relief with coeliac plexus blockade is generally transient at best[1], and surgical denervation procedures are seldom practised nowadays. Endoscopic manoeuvres, such as pancreatic sphincterotomy and stenting with or without extracorporeal shockwave lithotripsy[2,3], may help selected patients with isolated stricture and duct calculi, but they may be less appropriate in those with extensive fibrosis and calcification. Operative drainage of a dilated pancreatic duct and/or pseudocyst is both safe and effective[4,5], but in the authors' experience barely one-third of patients present a suitable 'target' for drainage. Resectional surgery carries a greater operative risk and may precipitate diabetes and steatorrhoea; it should be reserved for those with severe disease who are unsuitable for any drainage procedure. Total pancreatectomy must be considered when all else fails[6–8], but in patients with residual endocrine function partial pancreatectomy tailored to the maximal site of disease is often the best option[9–11].

Recent years have seen a trend towards resection of the head of the pancreas when this is involved in an inflammatory mass. Complications of chronic pancreatitis such as bile duct stricture, duodenal stenosis and portal vein compression are additional indications. Duodenum-preserving resection of the head of the pancreas (DPRHP) and the Frey variant of this procedure[12–14] are superficially attractive because of the limited number of anastomoses required, but retention of the duodenum as an endocrine organ is of unproven value[15]. The advantage of pancreatoduodenectomy over duodenum-preserving resection is that the procedure is appropriate for benign or malignant disease (the differential diagnosis may be extremely difficult)[16–18] and so it is familiar to all pancreatic surgeons. Preservation of the pylorus should reduce the physiological deficit associated with the classical Whipple resection which incorporates a distal gastrectomy[19–24].

The results of pancreatoduodenectomy in a personal series of 52 patients with chronic pancreatitis support the use of this major operation for those with severe disease of the pancreatic head; the pylorus was preserved in all but seven patients.

Patients and methods

Patients

Between November 1979 and November 1994, a consecutive series of 52 patients received proximal pancreatoduodenectomy for severe chronic pancreatitis under the care of the senior author at the Bristol Royal Infirmary ($n = 12$) or the Hammersmith Hospital, London ($n = 40$). There were 13 women and 39 men of mean age 42·2 (range 12–70) years. Patients who had either completion proximal pancreatectomy after previous distal resection ($n = 16$) or one-stage total pancreatectomy ($n = 17$) were excluded from the series and are reported elsewhere[8]. The operative technique of pancreatoduodenectomy with or without gastrectomy has been described previously[25–27].

Investigations

The pancreas was imaged in all patients by ultrasonography and contrast-enhanced computed tomography (CT); in recent years spiral CT has yielded improved imaging. Biliary and pancreatic ductal anatomy was delineated by endoscopic retrograde cholangiopancreatography (ERCP) in 42 patients, while four had

Presented to the 75th Annual Meeting of the Association of Surgeons of Great Britain and Ireland in London, UK, June 1995
Paper accepted 24 December 1995

percutaneous transhepatic cholangiography. The usual reason for not carrying out ERCP was technical failure because of duodenal stenosis, previous Pólya gastrectomy or distortion by a pseudocyst. Selective coeliac and superior mesenteric angiography with both arterial and venous phases was carried out in 34 patients to identify vascular abnormalities and determine whether there was inflammatory encroachment or occlusion of the great veins[28]. Seven patients had barium meal radiography to investigate the cause of vomiting. The pancreatic ductal tree was further evaluated by intraoperative pancreatography in 25 patients, generally by retrograde cannulation of the duct at the point of transection in the neck of pancreas[29]. Retrograde ductography was indicated particularly when ERCP had failed to demonstrate the upstream duct because of distortion or stricture of the duct in the head.

Endocrine function was assessed by a standard 75-g oral glucose tolerance test (OGTT), and exocrine function was estimated by the pancreolauryl test (normal above 30 per cent)[30] or, in three patients, by measuring 3-day faecal fat content (normal below 15 mmol/day). Immediately before discharge from hospital, the pancreolauryl test was repeated in 35 patients and the OGTT in 43 The glucose tolerance curve, derived from venous plasma samples, was classified according to World Health Organization criteria as normal if fasting and 120-min levels were both less than 7·8 mmol/l; impaired if fasting level was greater than 7·8 mmol/l and 120-min level between 7·8 and 11·1 mmol/l, and diabetic if fasting level was greater than 7·8 mmol/l and 120-min level above 11·1 mmol/l[31].

Follow-up

Follow-up information was derived from the hospital notes of patients still attending the outpatient clinics, from letters or telephone calls to referring general practitioners, physicians or surgeons of those no longer attending the hospital, or from letters directly to patients.

Statistical analysis

Student's *t* test was used to compare preoperative and postoperative results of OGTT and pancreolauryl tests, either the two-tailed test for unpaired samples or the one-tailed test for paired samples.

Results

Aetiology

There was a history of long-standing excessive alcohol intake in 34 patients, of whom 28 were men and six women. In addition to alcoholism, two of these had pancreas divisum, one had an annular pancreas and one was found to have a small and unsuspected neuroendocrine tumour within the resected head of pancreas. Chronic inflammation in five patients, one of whom had a choledochal cyst[32], was attributed to recurrent attacks of idiopathic acute pancreatitis. The remaining 13 patients (nine men and four women) did not give a history of excessive alcohol ingestion or have any relevant family history and were regarded as having idiopathic chronic pancreatitis. It was particularly in this group that the suspicion of cancer arose, the presenting feature often being obstructive jaundice.

Clinical presentation (Tables 1 *and* 2)

All but four patients were referred from outside the immediate hospital catchment area by consultant physicians or surgeons and two of the local patients were referred by physicians. Abdominal pain was the predominant symptom, being present in 47 patients (90 per cent). It manifested as either chronic persistent pain or frequent, recurrent attacks of pain requiring hospital admission. Three patients had previously had a coeliac plexus block. Regular daily use of oral narcotic analgesics was documented in 29 patients, while a further 14 required narcotics on an intermittent basis. Obstructive jaundice was the presenting complaint in 19 patients (37 per cent); 15 of these also had pain of varying severity. In five the jaundice was transient, while in five it was relieved before referral by endoscopic stent insertion (three) or cholecystojejunostomy (two). Bile duct stricture was demonstrated in 25 patients, and pseudocysts ranging from 3 to 9 cm in diameter were present in 14; seven had both pseudocyst and bile duct stricture. Calcification was present in the pancreatic head mass in 37 patients (71 per cent), although it was minimal in eight. In six patients vomiting was a prominent symptom, in addition to chronic pain; five had inflammatory duodenal stenosis and one had alcoholic pancreatitis in an annular pancreas[33].

Suspicion of pancreatic cancer was a real concern in 12 patients (*Table 1*). These patients presented with biliary or duodenal obstruction and had a pancreatic head mass but little or no pancreatic calcification (*Fig. 1*). One man had neither pain nor jaundice, but routine blood screen revealed a raised level of alkaline phosphatase; ultrasonography showed dilated bile and pancreatic ducts, and ERCP showed strictures of both ducts.

Sixteen patients had undergone previous upper abdominal operations, including cholecystectomy (eight), cholecystenterostomy (two, one with gastroenterostomy), transduodenal sphincteroplasty (two) and one each of the following: laparotomy and T tube insertion, cholecystostomy, excision of a choledochal cyst, Pólya partial gastrectomy and pseudocystojejunostomy. Three patients had indwelling biliary endoscopic stents and two had had pseudocysts aspirated.

Table 1 Indication for operation in 52 patients who underwent pancreatoduodenectomy for severe chronic pancreatitis

Main indication for operation	No. of patients
Abdominal pain alone	26
Pain and jaundice	15
Painless jaundice	4
Vomiting (and pain)	6
Suspicion of cancer*	1

*The possibility of cancer contributed to the decision for operation in a further 11 patients with either painless jaundice (four patients) or pain associated with jaundice (three), bile duct stricture (two) and duodenal stricture (two)

Table 2 Associated features in 52 patients who underwent pancreatoduodenectomy

Associated feature	No. of patients
Duodenal obstruction	6
Biliary stricture	25
Pseudocyst	14
Calcification	37
Portal hypertension	3

Preoperative pancreatic function

Two patients were already insulin-dependent diabetics at the time of referral. A preoperative OGTT was carried

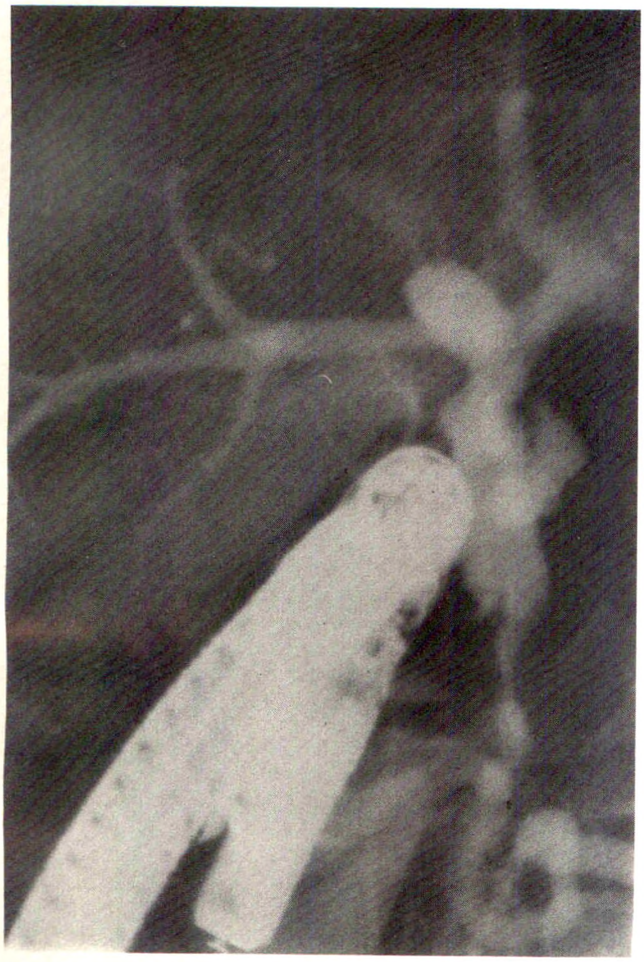

Fig. 1 Endoscopic retrograde cholangiopancreatography in a 30-year-old man who presented with a short history of painless obstructive jaundice. The cholangiogram shows a tight and irregular stricture which was thought to be malignant. The resection specimen confirmed severe (idiopathic) chronic pancreatitis and no evidence of carcinoma. The patient is alive and well 6 years later

out in 43 of the remaining 50 patients. The OGTT was normal in 28 patients, impaired in ten and diabetic in five.

Fourteen patients were taking pancreatic enzyme supplements at the time of referral. Pancreatic exocrine function was measured before operation in 39 patients. Three had 3-day faecal fat measurements and 36 pancreolauryl tests. One faecal fat estimation was below 15 mmol/day, two pancreolauryl tests were completely normal at 65 and 43 per cent, and three were just above normal (30–35 per cent). Three-day faecal fat estimations were abnormal in two, and pancreolauryl ratios were clearly abnormal in 31 patients: ten between 20 and 29 per cent, 11 between 10 and 19 per cent and ten below 10 per cent. Objective evidence of exocrine insufficiency was, therefore, present in 33 of the 39 patients tested, while 20 were considered to have exocrine failure.

Operations

The preferred operation of pylorus-preserving proximal pancreatoduodenectomy (PPPP) was performed in 45 patients (87 per cent) (*Fig. 2*). Mean length of duodenum preserved was 3·9 (range 1·5–5·5) cm. Seven patients had a conventional Whipple resection including partial gastrectomy because of gross duodenal inflammation and stenosis (four), concomitant gastric carcinoma (one)[33], previous Pólya gastrectomy (one) or active duodenal ulceration (one). The standard reconstruction comprised end-to-end pancreaticojejunostomy, end-to-side choledochojejunostomy and end-to-side duodenojejunostomy (or gastrojejunostomy in Whipple operations). The pancreaticojejunostomy was stented with an infant feeding tube in 21 patients with a small duct.

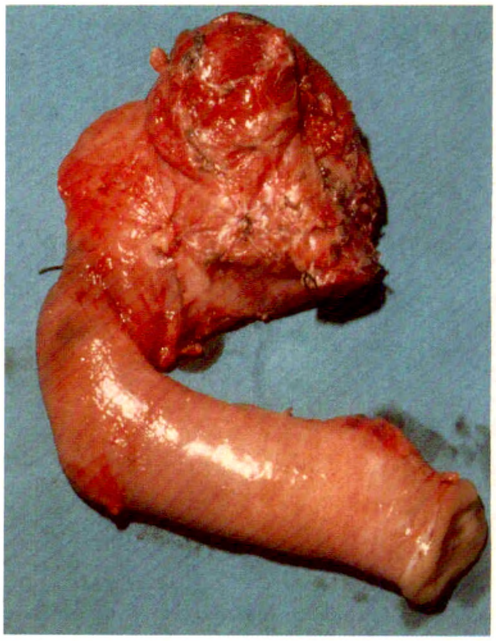

Fig. 2 Operative specimen from a pylorus-preserving proximal pancreatoduodenectomy showing a large inflammatory mass in the pancreatic head in a 45-year-old man with chronic alcoholic pancreatitis

Pancreatography was performed during 25 operations to assess the current state of the duct in the body and tail of the pancreas. In 15 patients with a dilated duct at the neck of pancreas, drainage of the distal gland was combined with resection of the head. Preoperative and/or intraoperative imaging confirmed dilatation of the distal duct (*Fig. 3*), which often contained further calculi. In these patients a modification of the pancreatic anastomosis was performed with a side-to-side anastomosis of the jejunum to the longitudinally incised pancreatic duct (*Fig. 4a*). Mean length of longitudinal pancreaticojejunostomies was 8 (range 5–11) cm.

The gallbladder was not removed routinely; it was preserved in 34 patients (65 per cent). Cholecystectomy had been carried out in the past in eight patients and was included in the operation in ten. In 11 patients the septum between the divided cystic duct and common hepatic duct was slit longitudinally to provide a wider biliary–enteric anastomosis, and in three patients the gallbladder was anastomosed to the jejunum in addition to the choledochojejunostomy to provide an additional biliary outlet when the common bile duct was very small and inflamed (*Fig. 4b*). The biliary–enteric anastomosis was stented with a T tube in 16 patients. No patient with a retained gallbladder developed cholecystitis in the postoperative period, but one was subsequently found to have gallstones.

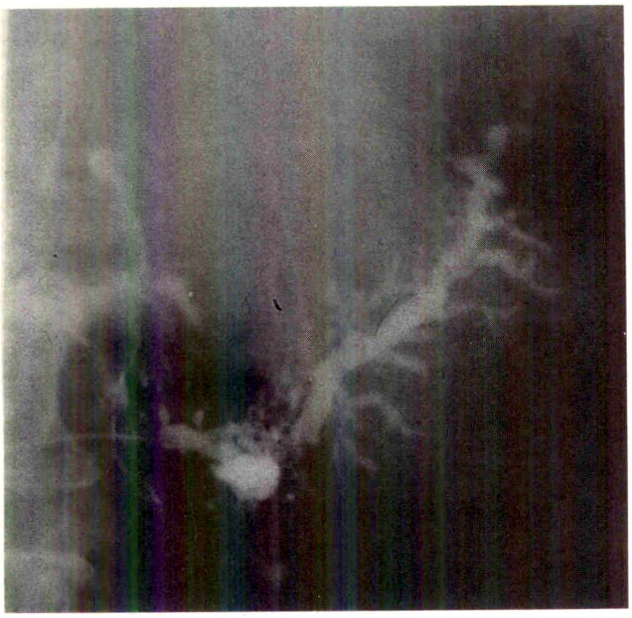

Fig. 3 Retrograde operative pancreatogram obtained by cannulation of the pancreatic duct in the neck of pancreas during proximal pancreatoduodenectomy. There is dilatation of the duct in the body and tail, which was managed by concomitant duct drainage

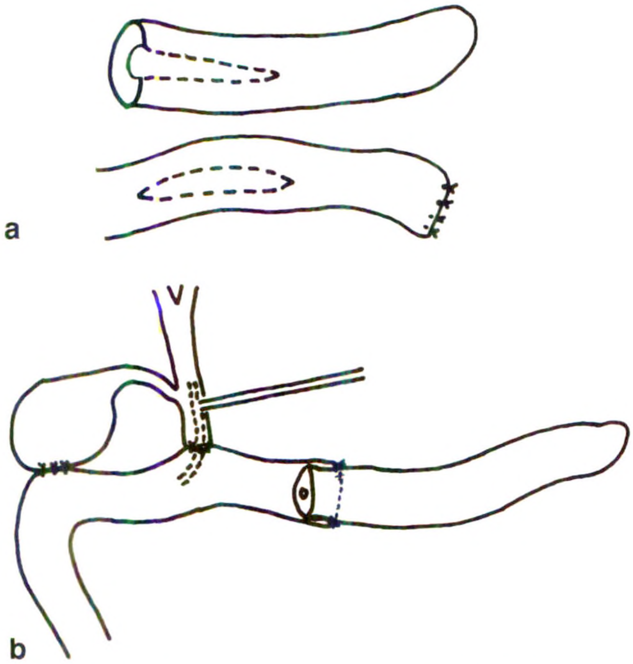

Fig. 4 Additional operative techniques during proximal pancreatoduodenectomy. **a** For a dilated distal pancreatic duct, side-to-side pancreaticojejunostomy is performed after longitudinal incision of the duct. **b** For a tiny thick-walled bile duct, a T tube is used to stent the choledochojejunostomy and a concomitant cholecystojejunostomy is created

Mean operating time was 6·2 (range 4·5–9·5) h and mean blood loss 2·7 (range 0·2–13·0) litres. Mean postoperative hospital stay was 18·3 (range 9–60) days. Twenty-four patients had complications; in these the postoperative stay was 23·9 (range 11–60) days compared with 12·5 (range 9–15) days for those with uncomplicated recovery. Complications included delayed return to normal eating (nine patients), intra-abdominal collections (eight), wound sepsis (ten) and transient leaks from the biliary anastomosis (three) or pancreatic anastomosis (two). One patient had early reoperation for evacuation of a haematoma and five had percutaneous aspiration or drainage of intra-abdominal collections. Two collections comprised amylase-rich fluid and three contained bile. The remaining collections resolved spontaneously with antibiotic treatment (one) or by discharging through the previous drain site (two). Seven of the ten patients with wound sepsis had no other complications, and hospital stay for them was a mean of 16 (range 11–27) days.

Two of those who had delayed return to normal eating had protracted conservative management before being re-explored; both had hold-up not at the pylorus but at the point of transit of the jejunum behind the transverse mesocolon, one because of herniation and one because of adhesions. The other seven had gastric atony. One of these patients who had a Whipple resection for tight duodenal stenosis had had prolonged gastric outlet obstruction before operation. The remaining six (12 per cent) had delayed gastric emptying after PPPP; of these two had associated wound sepsis, one had an intra-abdominal collection (aspirated percutaneously), one had haematemesis on day 10 (settled with omeprazole) and one had had partial gastric outlet obstruction before operation. All patients regained their preoperative weight, and most had improved appetite and body-weight secondary to the relief of pain.

Postoperative pancreatic function

Of 28 patients who had a normal preoperative OGTT, four were not retested after operation, 15 remained normal on postoperative testing, and nine deteriorated (seven impaired, two diabetic). Of ten patients with an impaired preoperative test, three remained impaired after operation while seven improved to normal. Of five patients with a diabetic test before operation, one was not retested, one remained diabetic and three improved (two normal, one impaired). Overall, glucose tolerance deteriorated in nine patients, remained static in 15 and improved in ten. Finally, in seven patients not tested before operation, the postoperative OGTT was normal in four and diabetic in one, while two did not have a postoperative OGTT. Two patients required insulin as an immediate consequence of the resection. The overall results show an increase in fasting blood glucose level as a result of operation, but no significant difference for the 2-h glucose level (*Table 3*). Among the 29 patients with combined preoperative and postoperative data, both mean fasting and 2-h values were higher after proximal pancreatoduodenectomy (*Fig. 5*).

Pancreolauryl tests were carried out after operation in 35 patients (*Table 3*), and all were below 30 per cent; only four were above 20 per cent. Among 23 patients who had repeat tests, exocrine function had deteriorated in 13, improved slightly in eight and remained unchanged in two (*Fig. 6*). Mean postoperative pancreolauryl ratio was significantly lower both overall and among the subgroup of patients with combined preoperative and postoperative data.

On long-term follow-up a further 14 patients became frankly diabetic, requiring insulin (six) or glibenclamide (four). In four the diabetes was a direct consequence of

Values are mean(s.d.). Several patients had either preoperative or postoperative testing but not both. OGTT, oral glucose tolerance test. *Student's *t* test

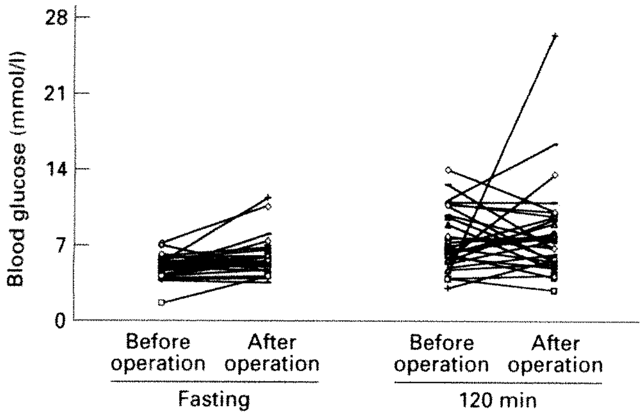

Fig. 5 Oral glucose tolerance tests in 29 patients with both preoperative and postoperative data. Individual values are plotted. Mean(s.d.) fasting blood glucose levels were 4·99(1·10) and 5·78(1·74) mmol/l before and after operation respectively ($P = 0·014$). Respective 120-min levels were 7·53(2·82) and 8·26(4·51) mmol/l ($P = 0·003$)

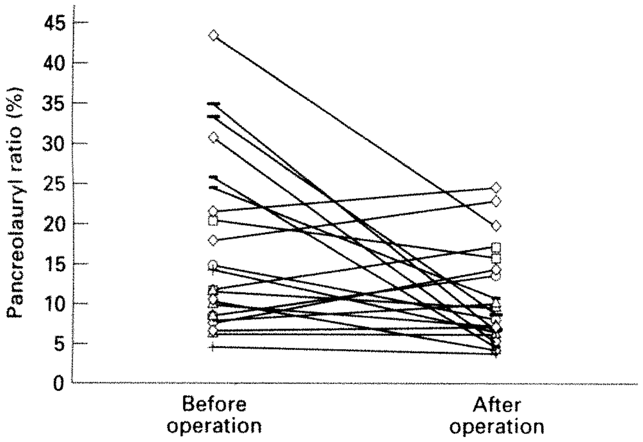

Fig. 6 Pancreolauryl tests in 23 patients with both preoperative and postoperative data. Individual values are plotted. Mean(s.d.) pancreolauryl ratios were 16·93(10·50) and 10·94(5·78) per cent before and after operation respectively ($P = 0·017$)

completion pancreatectomy, but ten deteriorated later after proximal pancreatoduodenectomy alone; of these three had a diabetic curve after operation, but the other seven developed progressive disease. Pancreatic exocrine insufficiency has been much commoner; 42 patients subsequently required pancreatic enzyme supplements to control steatorrhoea. Three of the ten patients who have not taken enzymes had postoperative pancreolauryl ratios below 15 per cent.

Late outcome

Median follow-up is 54 months (range 6 months to 15 years). Of the 47 patients who had pain at presentation, 37 had satisfactory relief of pain; 22 no longer require analgesics, and 15 with some residual pain use non-narcotic analgesics on an intermittent basis. Ten patients still required narcotics after the operation, and six of these have proceeded to completion pancreatectomy at a mean of 28 (range 7–51) months after pancreatoduodenectomy. One had chronic pain due to mesenteric vascular occlusive disease (which required two operations and ultimately led to death), two are addicted to narcotics and have declined completion pancreatectomy, and one has a much lower narcotic requirement.

Among the subgroup of 15 patients with distal duct drainage in addition to proximal resection, 11 have had worthwhile relief of pain, one is addicted to narcotics and three have received completion pancreatectomy.

Four patients developed late stricture of the biliary–enteric anastomosis and required either surgical revision to hepaticojejunostomy (two) or percutaneous dilatation (two). One of the four, who had a small inflamed bile duct at the original operation, had received a gallbladder anastomosis as well as the choledochoenterostomy. One other patient was reoperated on for adhesions at 6 months.

Ten patients have died (*Table 4*), seven from unrelated diseases, one from unknown cause, one from alcoholic liver disease and one from adult respiratory distress syndrome following an operation for strangulated adhesional obstruction of the small bowel.

Table 4 Details of patients who died after pancreatoduodenectomy

Sex	Age at operation (years)	Post-operative survival (months)	Operation	Cause of death
F	37	54	PPPP	Mesenteric vein thrombosis
M	38	90	PPPP	Strangulated obstruction
M	35	100	PPPP	Sudden death from unknown cause
F	42	71	PPPP and completion pancreatectomy	Acute asthma
M	46	38	Whipple	Acute myocardial infarct
M	52	83	PPPP	Oral carcinoma
M	41	84	Whipple	Liver failure
M	52	3	PPPP	Metastasis
M	51	60	Whipple	Bronchopneumonia
M	70	9	PPPP	Congestive cardiac failure

PPPP, pylorus-preserving proximal pancreatoduodenectomy

Discussion

Pancreatoduodenectomy achieved satisfactory relief of symptoms in over 80 per cent of this group of patients who clearly had severe chronic pancreatitis as indicated by the frequency of calcification, pseudocyst, bile duct stricture and duodenal stenosis. This result was achieved without any hospital deaths, but at the cost of a major operation lasting about 6 h and associated with substantial blood loss in several patients and a complication rate of 46 per cent. It is notable that 21 of the 52 patients had had previous pancreatobiliary procedures, either operative or non-operative.

The major advantage of pancreatoduodenectomy over DPRHP is the security of adequately removing a cancer, which was suspected in nearly a quarter of patients in this series and actually coexisted in one of them. In one series, four of 66 patients with a mass in the head of pancreas who were considered for DPRHP required conversion to pancreatoduodenectomy after a malignant tumour was found on frozen-section biopsy[12]. This event occurred in five of 43 patients in another series[34], and it led to the exclusion of one patient from a controlled prospective trial comparing DPRHP and PPPP[35]. From the technical standpoint DPRHP is just as difficult an operation as pancreatoduodenectomy, and it carries its own list of serious complications including (among 128 patients[13]) acute pancreatitis (11 per cent), haemorrhage from the cut surface of the pancreas (9 per cent), failure to relieve biliary obstruction (5 per cent) and ischaemic duodenal necrosis with fistula formation (1 per cent); none of these problems was encountered in the present series. Moreover, in 17 per cent of those with stenosis of the common bile duct, the decompressive effect of resection was inadequate and an additional anastomosis to the distal common bile duct was required[13].

There were small but significant reductions in exocrine and endocrine function after pancreatoduodenectomy, but these were of limited clinical importance since most patients already had preoperative exocrine impairment and only two required insulin as an immediate consequence. The endocrine data are similar to those the authors reported previously in a smaller group of patients[30], but a significant reduction in the pancreolauryl ratio emerges from this larger experience. The incidence of exocrine impairment before operation (85 per cent) was identical to that reported by Beger and colleagues[13] in a similar series of patients with severe inflammation of the pancreatic head, and 100 per cent (97 per cent in Beger's series) of those tested after operation had abnormal exocrine function. It has been claimed that an important advantage of DPRHP over pancreatoduodenectomy is the maintenance of a more physiological control of blood glucose[15]. In a prospective trial with 20 patients in each arm, DPRHP gave better results than PPPP in terms of both pain relief and endocrine function[35], but the analgesic effect of PPPP was surprisingly poor and follow-up was very short and incomplete[36]. The present results show that excision of the pancreatic head is unlikely to precipitate diabetes, in contrast to an equivalent resection of the distal gland[30]. A small proportion of patients became diabetic on long-term follow-up, which accords with the natural history of the disease[13].

The operation failed to abolish pain in ten of 47 patients, but the 12 per cent rate of subsequent completion pancreatectomy is broadly similar to that associated with distal pancreatectomy in the authors' experience. Pancreatoduodenectomy does not have the late attrition rate of total pancreatectomy. Only two deaths in this series could be attributed to the disease or the operation, whereas in an earlier series of total pancreatectomy for chronic pancreatitis, 29 per cent of patients died later from disease-related causes[8]. The 19 per cent death rate at a median of 60 months in the present series is lower than the 34 per cent at 5 years (rising to 46 per cent at 11 years) in a previous series from France[37]. All 50 patients in the French series had alcoholic pancreatitis, and all had a conventional Whipple operation with hemigastrectomy. Continued alcohol abuse was clearly linked with premature death, while several other patients died from smoking-related diseases. These conclusions are supported by a multivariate analysis of 2015 patients with chronic pancreatitis which showed, first, that survival was significantly less than in the background population and, second, that age at diagnosis, smoking and alcohol abuse were predictors of premature death[38].

Because the gastroduodenal artery is divided during pancreatoduodenectomy, particular care must be taken not to devascularize the bile duct by damaging its collateral supply from the right and left hepatic artery[39]. Pericholangitis seen in advanced pancreatitis can make for a difficult biliary reconstruction. In those with a small-diameter bile duct, retention of the gallbladder and division of the septum between cystic duct and common hepatic duct to widen the biliary orifice facilitates the anastomosis and may help to prevent (or circumvent) late biliary–enteric stricture. Although retaining the gallbladder is unconventional, no complications were encountered as a consequence, and this manoeuvre may assist biliary reconstruction in a difficult case. By contrast, pancreatic reconstruction is generally simpler and safer after resection for benign than malignant disease, because the associated fibrosis supports the placement of sutures and the enzyme content of the pancreatic juice is low[27]. Two patients had trivial pancreatic leaks, which presented with collections of juice with a high amylase content and which resolved after percutaneous drainage.

The principle of conservative resection for benign disease, which underlies retention of a healthy gallbladder, extends to preservation of the pylorus and duodenal cap except in the few patients with duodenal ulceration or stenosis. Although postoperative weight gain has been satisfactory, there is little objective proof that PPPP is better than resection including hemigastrectomy. Delayed gastric emptying in the postoperative period was a problem in only six patients with PPPP, and a possible contributory cause (notably sepsis) was found in five of these. Interestingly, one patient with pre-existing outlet obstruction had delayed gastric emptying after conventional Whipple resection. The 12 per cent incidence of postoperative gastric atony compares with widely varying rates of 5–51 per cent in other series of patients with PPPP[24]. Gastric emptying of liquids and solids was investigated isotopically in this laboratory in 24 patients with PPPP and 12 with a Whipple resection at a median of 5 months after operation[24]. Irrespective of the type of operation, liquid emptying was delayed in about 50 per cent of the patients and solid emptying in 60–80 per cent, while attendant symptoms were scarce. Surprisingly, therefore, antrectomy does not seem to prevent gastric atony, although retention of the pylorus protects against duodenogastric reflux.

The onset of obstructive jaundice (or duodenal stenosis) in a patient with painful chronic pancreatitis is a clear indication to consider operation; jaundice in the absence of pain raises the spectre of carcinoma. The importance of a biliary stricture without jaundice is, however, contentious. The early changes of secondary biliary cirrhosis seen in one study of patients with chronic pancreatitis and bile duct stricture[40] were conspicuously absent in another study, in which liver biopsy merely showed evidence of cholestasis[41]. Although further data are required, it would seem unwise to delay operation too long in those with persistently raised levels of liver enzymes in the blood; alcoholic liver disease is surprisingly uncommon in patients with chronic pancreatitis[42].

There is a definite group with chronic pancreatitis whose members are most effectively helped by resecting the head of the pancreas. The authors are not yet convinced about the physiological superiority of DPRHP over PPPP and favour the more complete resection because of the frequent concern about cancer as well as its greater technical simplicity. Finally, if there is extensive distal disease, resection of the head can sometimes be combined with duct drainage in the body and tail. The authors have used retrograde ductography to demonstrate ectasia and calculi in the distal duct, since radiography is more informative than simple probing of the duct; intraoperative ultrasonography might also be valuable in this context. In these patients with advanced disease, even the combination of proximal resection and distal duct drainage can sometimes fail and necessitate completion pancreatectomy.

Angled metal cholangiography cannula for laparoscopic cholecystectomy

N. D. KARANJIA, D. BANERJEE and
G. H. DICKSON
Department of Surgery, Worthing Hospital, Park Avenue, Worthing BN11 2OH, UK
Correspondence to: Mr G. H. Dickson

Laparoscopic techniques for peroperative cholangiography are more complex, and only 25 per cent of surgeons perform this procedure either routinely or selectively[1]. This may be because some surgeons find it difficult, time-consuming or expensive.

A simple metal cannula that renders peroperative cholangiography easy during laparoscopic cholecystectomy is described. A similar cannula has been used for open cholecystectomy[2].

Surgical technique

Laparoscopic cholecystectomy is performed using four cannulas. Once the structures in Calot's triangle have been dissected and defined, peroperative cholangiography is carried out with a metal cholangiography cannula (Misco Medical, Thorpe Bay, UK) (*Fig. 1*). This is 28 cm long, has an olive-shaped end with two lateral eyes and has a 45° bend approximately 2·0 cm from the end. It costs UK £25 and it is not reusable. It is inserted into the abdominal cavity through a 14-G, 13-cm angiocath placed between the epigastric and subcostal cannulas. After removing the inner needle, the hub of the angiocath is cut off and, while the surgeon holds the plastic firmly, the metal tip of the cannula is passed through the catheter. It is important to introduce the needle parallel to the grasping forceps holding Hartmann's pouch and to have the angled tip parallel to the cystic duct before cannulation. After incising the cystic duct, it is milked backwards with forceps to remove any small stones. The cannula may then be placed into the cystic duct. A clip is tightly applied just proximal to the olive to hold the cannula in place. The grasping forceps holding Hartmann's pouch may then be removed. The graspers on the fundus of the gallbladder may be left in place and the other cannulas (umbilical and epigastric) may be retracted appropriately. Cholangiography is then performed using an image intensifier.

Paper accepted 10 December 1995

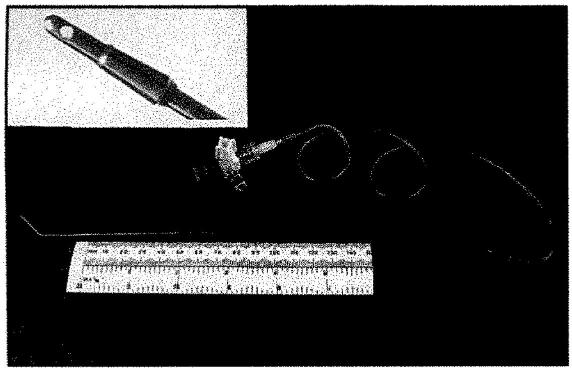

Fig. 1 Misco Medical catheter cholangiography needle

Patients

Data were prospectively collected on 173 consecutive patients undergoing laparoscopic cholecystectomy with routine cholangiography.

A good quality cholangiogram was defined as one showing clear pictures of the cystic duct leading to the confluence of the common hepatic and common bile ducts, with clear views of the right and left hepatic ducts and their sectoral branches, and showing the terminal common bile duct with contrast flowing into the duodenum.

The time taken to perform cholangiography in 43 consecutive patients from clipping the cystic duct at the gallbladder end to clipping the cystic duct at its central end, just before its division, was recorded.

Results

Good-quality peroperative cholangiograms were obtained in 171 (98·8 per cent) of 173 patients; there was slight extravasation of contrast in two patients but, despite this, the pictures were satisfactory. In two patients a cholangiogram could not be obtained as the cystic duct was small and tortuous and could not be cannulated. The mean time for cholangiography was 15·2 (range 9–33) min.

Discussion

Insertion of a cannula into the common bile duct via the cystic duct is the safest method for performing peroperative cholangiography[3]. Most cannulas are flexible and awkward to introduce during laparoscopic cholecystectomy. They often impact on the spiral valve of Heister. At open operation the cystic duct is often gently dilated by a probe and the valve can be broken down. This is more difficult at laparoscopic cholecystectomy and may introduce gas bubbles into the system. One advantage of the metal cannula is that its blunt olive end acts as its own dilator and the cannula usually slips into the cystic duct with ease.

If a flexible cannula is used, the clip holding the cannula within the cystic duct cannot be tightly applied in case the catheter narrows; consequently, there is a risk that the cannula may slip out or that dye may extravasate. The clip used to hold the metal cannula in place may be applied tightly without the prospect of narrowing the cannula; the blunt olive impacts into the clip and prevents extravasation of contrast.

The metal cannula has not been known to cause any injury to the bile ducts in the authors' series. It has made peroperative cholangiography for laparoscopic cholecystectomy a quick and easy procedure which is possible in almost 99 per cent of patients.

Hepatobiliary anatomy in patients with transposition of the gallbladder: implications for safe laparoscopic cholecystectomy

M. IDU, J. JAKIMOWICZ, A. IUPPA and A. CUSCHIERI*

*Departments of Surgery, Catharina Hospital Eindhoven, The Netherlands, and *Ninewells Hospital and Medical School, University of Dundee, UK*

Correspondence to: Professor A. Cuschieri, Department of Surgery, Ninewells Hospital and Medical School, University of Dundee, Dundee DD1 9SY, UK

The surgical anatomy of six patients with sinistroposition of the gallbladder is described. Five of these were encountered in a consecutive series of 1764 patients undergoing laparoscopic cholecystectomy for symptomatic gallstone disease in two hospitals between 1989 and 1994, a prevalence of 0·3 per cent in patients undergoing this operation. Despite the left-sided transposition of the gallbladder, the biliary pain experienced by these patients was always on the right side. Preoperative diagnosis of this anomaly was made in only one of six patients despite routine preoperative external ultrasonography and selective preoperative cholangiography. In sinistroposition the cystic artery always crosses in front of the common bile duct from right to left. The cystic duct may open on the left or right side of the common hepatic duct. The anomaly does not preclude safe laparoscopic cholecystectomy but modifications of the port sites and use of the falciform lift facilitate the procedure in these cases. The anatomical features of the sixth case encountered in a patient undergoing resection of hilar cholangiocarcinoma indicate that sinistroposition of the gallbladder may be due to failure of development of segment IV of the liver.

A left-sided gallbladder is an integral component of situs inversus[1]. In the absence of this condition, abnormal location of this organ is generally recognized as an uncommon anomaly. Thus, in 1964, a collective review of the Western literature yielded only 24 cases of left-sided gallbladder[2]. There have been other isolated reports of the condition since then[3,4]. Two types of gallbladder malposition in the absence of situs inversus have been described by Beck[5]: medioposition of the gallbladder and sinistroposition (transposition). In medioposition, the gallbladder is displaced medially to lie on the undersurface of the quadrate lobe but on the right side of the round ligament. In sinistroposition, the gallbladder lies under the left lobe (usually segment III) to the left of the round ligament. Despite its allegedly rare incidence, the authors have encountered six cases of sinistroposition. The resulting pathological anatomy has implications for the safe conduct of laparoscopic cholecystectomy and is described in this report.

Patients and methods

Five patients (four women) aged 21–42 years presented with episodes of biliary colic; gallstones were confirmed by ultrasonography. In all patients the common bile duct was normal on ultrasonography and preoperative liver function tests showed no abnormality. A preoperative diagnosis of left-sided gallbladder was made on the basis of external ultrasonography in one patient. In these five patients the attacks of colicky abdominal pain were in the classical position, i.e. in the right upper quadrant with radiation to the right back[2]. All patients were scheduled for laparoscopic cholecystectomy without preoperative cholangiography. The procedure was completed satisfactorily in four patients but converted to open cholecystectomy in one because of difficult dissection and bleeding from the cystic artery.

In addition to pain in the right upper quadrant, a sixth patient had clinical jaundice (bilirubin 100 μmol/l), a raised alkaline phosphatase level of 200 units/l and gross dilatation of the intrahepatic biliary tract on ultrasonography. Computed tomography showed an enlarged lymph node near the head of the pancreas. Endoscopic retrograde cholangiopancreatography (ERCP) confirmed the presence of a hilar stricture suggestive of a Klatskin cholangiocarcinoma. This patient was subjected to staging laparoscopy, which confirmed operability of the lesion and revealed transposition of the gallbladder. He was treated by radical resection of the tumour with left hepatectomy as the lesion was extending along the left hepatic duct.

Surgical anatomy

Prevalence. Five of the cases described in this report occurred in a consecutive series of 1764 patients undergoing laparoscopic cholecystectomy for symptomatic gallstone disease between 1989 and 1994, a prevalence of 0·3 per cent in those having this operation.

Liver. All cases were distinguished by a marked, deep and anterior-facing umbilical fissure with an apparent absence of the quadrate lobe of the liver (*Fig. 1*).

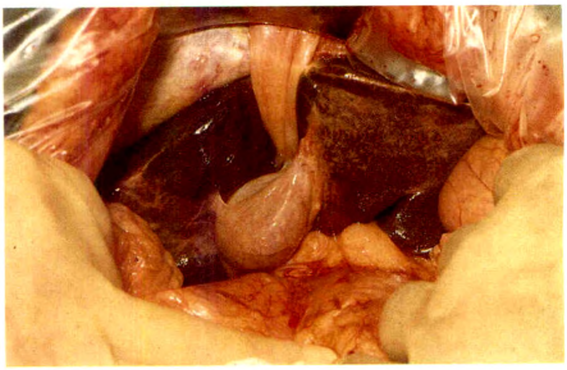

Fig. 1 Intraoperative finding of sinistroposition of the gallbladder in a patient undergoing resection of a hilar cholangiocarcinoma. The gallbladder is situated to the left of the round–falciform ligament complex and is suspended from the medial part of segment III with the fundus adherent to the undersurface of the right lobe. Note the deep anterior umbilical fissure. A segment IV bile duct could not be identified during extended resection including left hepatectomy

Paper accepted 14 January 1996

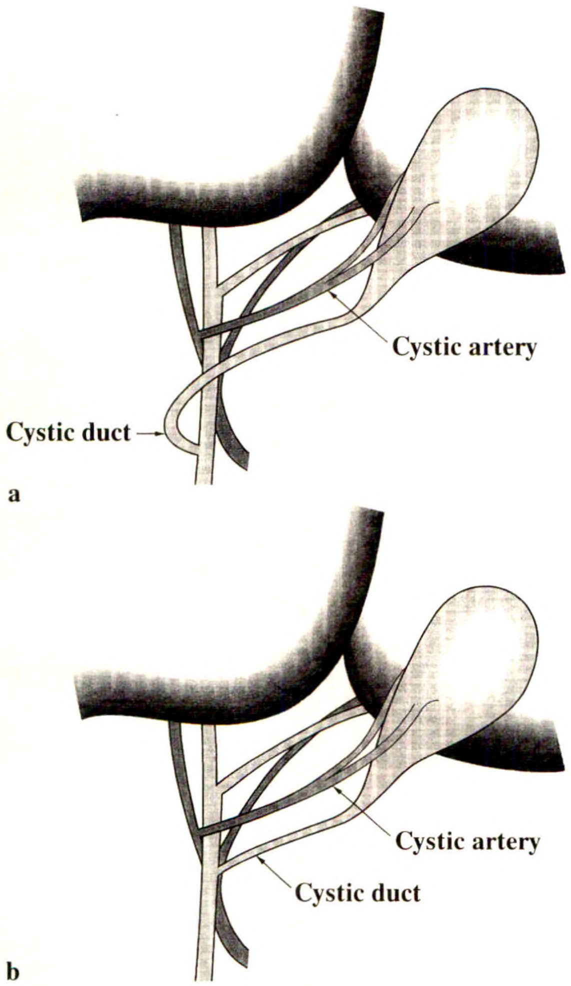

Fig. 2 Distribution of the cystic artery and cystic duct in sinistroposition of the gallbladder encountered in the present series. **a** Cystic duct crosses to join the hepatic duct on the right; **b** cystic duct joins the hepatic duct on the left

Evidence for the latter was confirmed in the patient undergoing radical resection of a Klatskin tumour with left hepatectomy, in whom a segment IV duct could not be identified arising from the left hepatic duct. The disposition of the structures in the porta hepatis of this patient was different from normal: the bile duct was anterior to the common hepatic artery and the portal vein lay behind the artery in the sagittal plane.

Relationship to round ligament. All the gallbladders were to the left of the round ligament and lay beneath segment III of the left lobe (*Fig. 1*).

Hepatoduodenal ligament. This was situated to the right of the round and falciform ligament in five patients and to the left (converted case) in one.

Origin and course of the cystic artery. In all cases the cystic artery was long. It originated on the right side of the common bile duct and coursed to the left in front of the bile duct to the gallbladder (*Fig. 2*).

Termination of the cystic duct. The cystic duct entered the left side of the common bile duct in three patients; in the other three it crossed anterior to the common bile duct before its entry on the right side (*Fig. 2*).

Discussion

On first inspection the transposed gallbladder is inconspicuous as it is overlapped by both the round and falciform ligaments and by the left lobe of the liver. The most useful simple procedure for improving exposure during laparoscopic cholecystectomy is the falciform lift, which lifts the central portion of the liver and moves the ligament off the operative field[6]. Although cholecystectomy can be carried out with the standard port sites, a better arrangement for laparoscopic removal of a left-sided gallbladder consists of more medial positioning of the gallbladder-retracting port and placement of the right-hand operating port well to the left of the midline. To some extent, the long cystic artery and duct facilitate the dissection but this should be kept to the left of the common bile duct and no attempt should be made to trace them to their origins.

Sinistroposition of the gallbladder (left-sided transposition) may not be as rare as generally believed, possibly because it is not recognized at open operation or because of under-reporting. The anomaly is obvious when viewed laparoscopically. Despite routine ultrasonography of the gallbladder in patients undergoing investigation for gallstone disease, diagnosis of the abnormal position is missed in the majority of cases and is not identified by contrast studies including ERCP. Sinistroposition of the gallbladder is probably the result of failure of development of the quadrate lobe of the liver, as suggested by the operative findings in the patient undergoing resection of hilar cholangiocarcinoma with left hepatectomy.

The ability of the angiogenesis inhibitor TNP-470 to prevent liver metastasis after partial hepatectomy, and whether TNP-470 impairs liver regeneration or skin wound healing, was evaluated. Following the injection of VX2 carcinoma cells into the portal vein of rabbits, half of the animals underwent resection of the middle hepatic lobe (hepatectomized group) and half did not (non-hepatectomized group). TNP-470 (50 mg) was infused continuously into the portal vein in both groups for 7 days, while controls received only water. The hepatectomized TNP-470-treated group had significantly fewer tumours (mean(s.e.m.) 23·3(12·3)) than the hepatectomized control group (123·7(24·4)). There was no significant difference in the 5-bromo-2′-deoxyuridine labelling index of regenerated hepatocytes between the TNP-470-treated and control groups. Wound healing in TNP-470-treated animals was not impaired. Intraportal infusion of TNP-470 prevents the recurrence of liver metastasis after partial hepatectomy without impairing healing or liver regeneration.

The transarterial infusion of anticancer drugs is often used for irresectable liver metastases. Unfortunately, this approach is rarely successful. Partial hepatectomy, however, has been shown to prolong the survival of patients with resectable liver metastases from colonic cancer[1–4]. Patients who undergo curative resection of a solitary colorectal metastasis have a 20–38 per cent 5-year survival rate[1–3]. None the less, 61–75 per cent of patients who undergo a 'curative' liver resection of a colorectal cancer metastasis develop a recurrence in the liver within 5 years of hepatectomy. Of these patients, 36 per cent develop a recurrence within 1 year of the hepatectomy[1,2].

Patients are often encountered who have a hepatic recurrence soon after hepatectomy, suggesting that the procedure itself might stimulate tumour growth[5,6]. The mechanisms for this are not clearly defined, but several possibilities have been suggested. For example, hepatocyte growth factor, which is released in order to stimulate liver regeneration, may also serve as a tumour growth factor[7,8]. It is also possible that surgical manipulation causes tumour cell implantation in the residual liver, or that the hepatectomy and transfusion cause immunosuppression. Thus, the prevention of recurrence in the residual liver after hepatectomy may improve the prognosis of patients with resectable liver metastases.

There have been several clinical studies of adjuvant regional chemotherapy for the residual liver after partial hepatectomy for resectable liver metastases[9]. However, the results of these studies have not been wholly satisfactory[3,9]. The reasons for this failure include the possibility that the initial tumours were not sensitive to currently available drugs, and the fact that several of the agents tested had severe toxicity which discouraged their use in an adjuvant setting[3,9,10].

On the other hand, as angiogenesis is essential for the proliferation of cancer cells, the inhibition of new blood vessel growth may be a useful way to prevent liver metastasis[11]. In addition, endothelial cells do not proliferate in adults, except in a few areas of the genital organs[12]. Therefore, if endothelial proliferation could be inhibited selectively, tumour growth might be suppressed. TNP-470, a new synthetic analogue of fumagillin isolated from *Aspergillus fumigatus*, is known to inhibit angiogenesis by inhibiting DNA synthesis selectively in endothelial cells. It is also known to have an antitumour effect[11–14].

The authors have already reported that continuous infusion of TNP-470 into the hepatic artery blocks liver metastasis more effectively than injections into the jugular or portal vein[15]. Thus, TNP-470 may be able to prevent tumour recurrence in the liver after partial hepatectomy. However, it is also possible that TNP-470 may inhibit liver regeneration and wound healing because of its suppression of angiogenesis. The purpose of this study was to investigate the efficacy of TNP-470 in preventing the development of liver metastasis after partial hepatectomy, and to determine whether TNP-470 inhibits liver regeneration and wound healing, using a rabbit model.

Materials and methods

Angiogenesis inhibiting agent

TNP-470 (*O*-(chloroacetyl-carbonyl)fumagillol) was obtained from Takeda Chemical Industries, Osaka, Japan. It was mixed with cyclodextrin to increase its solubility and stability in water.

Animals and tumour cells

Twenty-four Japanese white rabbits weighing 2·4–2·8 kg were used for the study. The experimental protocols followed the 'Guidelines for the Welfare of Animals in Cancer Research' established by the Committee of Kyoto Prefectural University of Medicine.

The carcinoma cells were maintained in rabbits under endotoxin-free conditions. The VX2 tumours were broken into fine pieces, filtered through a stainless steel mesh, and suspended

---

Paper accepted 7 January 1996

in Hank's balanced salt solution (HBSS) (Handai Biken, Osaka, Japan). The viability of the VX2 cells was confirmed by trypan blue staining.

Experimental procedure

The rabbits were anaesthetized with intravenous pentobarbital sodium 30 mg/kg. A laparotomy was performed through a midline incision. VX2 carcinoma cells ($1 \cdot 0 \times 10^6$)in 0·1 ml HBSS were injected into the superior mesenteric vein to produce liver metastases.

Following injection, half the rabbits underwent resection of the middle lobe of the liver (hepatectomized group), equivalent to 45 per cent of the total liver weight. The other rabbits did not undergo hepatectomy (non-hepatectomized group). The hepatectomy protocol was as follows: first, Glisson's triad into the middle lobe was ligated. The middle hepatic vein then was dissected from the liver parenchyma and ligated. The middle lobe was then removed and weighed.

TNP-470 was infused continuously for 7 days, because it has been reported that a drip infusion of TNP-470 has more efficacy and less toxicity than a bolus infusion[16]. An osmotic pump (model 2ML1; Alzet, Palo Alto, California, USA) was used for the continuous infusion of TNP-470. The pump has a 2-ml capacity and can infuse an agent at a constant rate (10 μl/h) for 7 days. Distilled water alone (2 ml) was used as a control. A polyethylene catheter, 1·22 mm in diameter (Becton Dickinson Labware, Franklin Lakee, New Jersey, USA), was connected to the pump and cannulated into the superior mesenteric vein of all animals. The treated groups (hepatectomized TNP-470-treated group, six rabbits; non-hepatectomized TNP-470-treated group, six) received 50 mg TNP-470, dissolved in 2 ml distilled water over 7 days (2·85 mg per kg per day). The control groups (hepatectomized control group, six rabbits; non-hepatectomized control group, six) received 2 ml distilled water only over 7 days. The skin and muscular layers were closed individually with a running suture of 1–0 Nurolon (Ethicon, Summerville, New Jersey, USA).

Assessment of efficacy and toxicity of TNP-470

Fourteen days after the beginning of the infusion, blood was sampled and analysed for serum glutamic–oxaloacetic transaminase (SGOT), serum glutamic–pyruvic transaminase (SGPT) and total bilirubin concentration. Thirty minutes after weighing the rabbits, 20 mg/kg 5-bromo-2′-deoxyuridine (BrdU) was infused intravenously. The rabbits then were killed and the liver was removed. The number of macroscopic tumours on the surface of each lobe of the liver was counted.

Evaluation of liver regeneration

A preliminary investigation in five rabbits indicated that the middle lobe of the liver accounted for a mean(s.e.m.) of 45(3) per cent of the weight of the entire liver. Therefore, the weight of the whole liver at the time of the partial hepatectomy (A) could be estimated as A = weight of the middle lobe/0·45.

The residual liver (B) was weighed 14 days after the partial hepatectomy. The liver regeneration ratio was defined as B/A.

For evaluating regeneration of the liver, the BrdU labelling index was calculated after staining with the avidin–biotin–peroxidase technique, with an anti-BrdU antibody. The livers of animals in the hepatectomized control and TNP-470-treated groups were fixed in 10 per cent formalin. Sections of 4 μm from each sample were dewaxed and stained with a monoclonal mouse anti-BrdU antibody (DAKO, Glostrup, Denmark) for 3 h. All endogenous peroxidase activity in the samples was blocked by incubation with 0·6 per cent hydrogen peroxide in methanol for 30 min. The samples were then incubated with a biotinylated anti-mouse immunoglobulin G (Vector Laboratories, Burlingame, California, USA) for 30 min, followed by staining with the avidin–biotin–peroxidase complex for 1 h. All incubations were performed in a moist chamber. Finally, the specimens were reacted with 3,3′-diaminobenzidine in 0·05 mol/l Tris buffer containing 0·02 per cent hydrogen peroxide for 3 min. The specimens were counterstained with haematoxylin, then dehydrated and mounted. The percentage of BrdU-positive nuclei in at least 1000 cells was determined for each specimen.

Evaluation of skin healing

To evaluate skin healing, blood flow in the incised skin was measured with a PeriFlux laser Doppler blood flow meter (Perimed, Stockholm, Sweden) and the tensile strength of the wound was determined with a spring tension meter.

The probe of the PeriFlux was placed on the skin incision of the anaesthetized animals and the blood flow was measured. All Nurolon sutures were removed, and the spring tension meter was attached 2 cm away from the wound. The wound was then stretched vertically about the site of the incision. After the bursting test, the blood flow in the muscular layer of the wound was determined.

Statistical analysis

All data are expressed as mean(s.e.m.). The results were analysed with Student's t test. $P \leq 0 \cdot 05$ was considered statistically significant.

Results

The mean(s.e.m.) number of tumours in the TNP-470-treated non-hepatectomized animals (12·3(5·4)) was significantly lower than that in non-hepatectomized controls (75·0(14·5)) (*Fig. 1*). In hepatectomized rabbits, the mean(s.e.m.) number of tumours in the TNP-470-treated group was also significantly lower than that in controls (23·3(12·3) *versus* 123·7(24·4) respectively.

There were significantly more metastatic liver lesions in the hepatectomized control group than in non-hepatectomized controls.

None of the TNP-470-injected animals exhibited significant weight loss compared with control rabbits. The SGOT and SGPT concentrations were no higher in TNP-470-treated animals than in controls. The total bilirubin level was not raised in any rabbit (*Table 1*).

The mean(s.e.m.) liver regeneration ratio of treated animals was 1·11(0·15) and that of the controls was 0·97(0·08), indicating that liver weight had returned to the prehepatectomy level by day 14. There was no significant difference in the mean(s.e.m.) BrdU labelling index between treated (15·5(2·5)) and control (15·2(4·1))

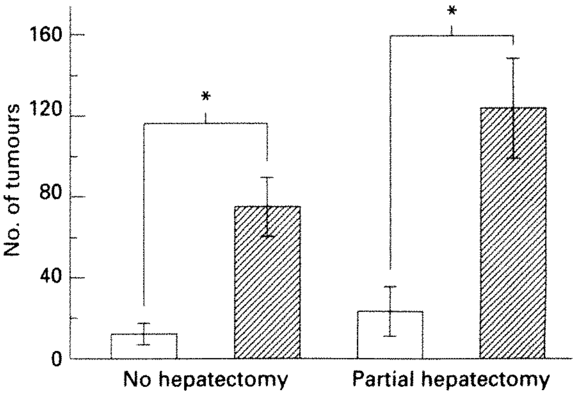

Fig. 1 Mean(s.e.m.) number of tumours in the liver of rabbits treated with TNP-470 (☐) and in controls (▨). $^*P < 0 \cdot 05$ (Student's t test)

Table 1 Effect of TNP-470 on weight loss and serum biochemistry

	Partial hepatectomy		No hepatectomy	
	TNP-470	Control	TNP-470	Control
Weight loss (g)	250(141)	91(55)	277(122)	477(42)
SGOT (units/l)	193·7(110·0)	330·5(122·5)	51·0(15·3)	73·0(29·1)
SGPT (units/l)	41·2(6·2)	99·8(27·2)	37·8(5·0)	31·2(6·9)
Serum total bilirubin (mg/dl)	0·32(0·05)	0·30(0·05)	0·25(0·04)	0·23(0·02)

Values are mean(s.e.m.). SGOT, serum glutamic–oxaloacetic transaminase; SGPT, serum glutamic–pyruvic transaminase. There were no significant differences between any of the groups

animals. Furthermore, no histological evidence of degeneration and/or necrosis was seen in the liver remnant of treated rabbits.

There was no significant difference in the mean(s.e.m.) blood flow in the skin around the incision between the treated group (45·3(13·8) units per mm^2) and the control group (42·5(14·9) units per mm^2). There also was no significant difference in the blood flow of the muscle layer between treated and control animals (41·0(12·3) *versus* 49·0(8·9) units per mm^2 respectively). A wound infection occurred in one rabbit in both treated and control groups.

The mean(s.e.m.) tension against wound bursting in the treated group did not differ significantly from that in controls (656(96) *versus* 650(134) g respectively).

Discussion

As reported by Panis *et al.*[6], partial hepatectomy accelerated the growth of liver metastases in the present study. The present authors have already reported that intra-arterial injection of TNP-470 prevents the proliferation of occult liver metastases[15]; thus, TNP-470 was expected to prevent the development of tumours in the liver remnant after partial hepatectomy. TNP-470 was injected into the portal vein, because about two-thirds of the hepatic blood is supplied from portal vein[17] and it was postulated that TNP-470 would have a greater influence on liver regeneration when administered by portal infusion. A further minor reason for intraportal injection was that cannulation at this site is technically easier than intra-arterial cannulation after hepatectomy.

Because the mean number of tumours in treated groups was significantly lower than that in untreated groups, TNP-470 infused through the portal vein may be effective in preventing growth of tumours in the liver remnant after resection of liver metastases. In the treated animals, the mean number of tumours in hepatectomized rabbits was slightly greater than that in those not undergoing hepatectomy. It is unclear whether assessing the tumour number at a later time would have made any difference.

In light of the ability of TNP-470 to inhibit angiogenesis, it was feared that it might impair liver regeneration or wound healing after operation. The side-effects of TNP-470 were evaluated using weight loss, SGOT, SGPT and total bilirubin concentrations as parameters. None of the TNP-470-injected groups suffered significant weight loss or liver dysfunction compared with controls. Therefore, the continuous intraportal administration of TNP-470 appears to have no severe adverse effects. Liver regeneration in TNP-470-injected animals was nearly complete by 14 days after hepatectomy, and was similar to that in untreated rabbits.

Why was tumour growth prevented, while liver regeneration was not impaired? Tumour cells implant primarily in the sinusoids, then migrate away and proliferate at some distance away from the vessels[18,19]. These cells need capillaries to supply nutrients and oxygen to support their growth. In contrast, hepatocytes are present along the sinusoids and can easily obtain oxygen and nutrition for proliferation. Furthermore, the endothelial cells of the sinusoidal capillaries have many intercellular and intracellular fenestrae. The sinusoidal capillaries vary in diameter and shape, and their anatomical flexibility is thought to be quite high[20]. Thus it is likely that hepatocytes can regenerate without the need for extensive proliferation of endothelial cells.

At first, it was postulated that the reason for there being no difference in wound healing between TNP-470-infused and control animals was that TNP-470 was injected into the portal vein. The metabolism of TNP-470 is not yet clearly defined, but if it occurs primarily in the liver, liver tumours may be exposed to fairly high concentrations of TNP-470 while the abdominal wall may be exposed to only low concentrations. However, in a previous experiment, intravenous and intraportal injection of TNP-470 yielded a similar efficacy in preventing liver metastasis[15], suggesting that this hypothesis is unlikely to be correct.

The abdominal wall was not examined for healing continuously after operation, but only on day 14 after surgery. Therefore, it is possible that angiogenesis and healing of the abdominal wound in TNP-470-injected rabbits might have lagged behind that of the control group during the first 7 days of TNP-470 infusion and then caught up with controls. If this hypothesis is correct, the number of induced capillaries needed to heal an abdominal wound may be less than that needed to nourish liver metastases. None the less, it is important to note that wound healing in TNP-470-treated animals was not inferior to that in controls by day 14. Thus, this study suggests that TNP-470 could be used in patients after operation, at least under certain conditions. The authors believe that TNP-470 can suppress the recurrence of liver metastasis after partial hepatectomy.

Acknowledgements

The authors thank Dr H. Okada and the Drug Delivery System Research Laboratories of Takeda Chemical Industries for supplying TNP-470, and Dr Okada for valuable comments on the study.

Cardiac complications after hepatic resection

K. YANAGA, K. TAKENAKA, K. YAMAMOTO, T. NISHIZAKI, K. SHIRABE, M. SHIMADA, N. KAWAHARA, A. CHISHAKI* and K. SUGIMACHI

Correspondence to: Dr K. Yanaga

During a period of 94 months between 1985 and 1993, 474 hepatic resections were performed in 451 patients, of whom 23 (5 per cent) had cardiac problems: ischaemic heart disease in 16 (previous myocardial infarction in five and angina pectoris in 11), arrhythmic disorders in three, valvular disease in three (previous mitral valve replacement in two) and hypertrophic cardiomyopathy in one. The cardiac patients had a higher incidence of cardiac complications (24 *versus* 0 per cent, $P<0{\cdot}0001$) including two myocardial infarctions, and of non-cardiac complications consisting of postoperative liver failure (16 *versus* 4 per cent, $P<0{\cdot}01$) and bile leak (16 *versus* 5 per cent, $P=0{\cdot}02$), as well as hospital death (16 *versus* 3 per cent, $P<0{\cdot}001$). However, long-term survival was similar in the two groups. Patients with preoperative cardiac conditions appear to be at increased risk for early postoperative morbidity and mortality after hepatic resection.

With refinements in the assessment of hepatic functional reserve, surgical techniques and postoperative care, elective hepatic resection is now regarded as a safe surgical procedure[1–5]. However, being a major surgical procedure of the upper abdomen with significant intraoperative blood loss and occasional interruption of splanchnic circulation, hepatic resection could be associated with a high rate of perioperative cardiac morbidity and mortality. Although cardiac risk factors for patients who undergo non-cardiac surgery in general have been established, little is known about the significance of concomitant cardiac conditions such as ischaemic heart disease on the outcome of resection of the liver[6,7]. The purpose of this study was to clarify the effect of preoperative cardiac conditions on the outcome of elective hepatic resection.

Patients and methods

During a period of 94 months from 1 April 1985 to 18 February 1993, 474 hepatic resections were performed in 451 patients in the authors' institution. Patients' ages ranged from 15 to 79 years with a mean(s.d.) of 58·5(9·6) years; 347 (77 per cent) were men. The hepatic resection was right or left trisegmentectomy in 30 patients, bisegmentectomy consisting of right or left lobectomy as well as central bisegmentectomy in 120, resection of one segment in 75, and subsegmentectomy or less in 249. Of the 451 patients, 23 (5 per cent) who underwent 25 hepatic resections had cardiac problems: ischaemic heart disease in 16 (myocardial infarction in five and angina pectoris in 11), arrhythmic disorders in three, valvular disease in three, and hypertrophic non-obstructive cardiomyopathy in one. A patient with sick sinus syndrome underwent three hepatic resections; two of the three patients with valvular disease had had mitral valve replacement. All cardiac patients with cardiac conditions were over 50 years of age and were assigned as New York Heart Association class I.

Of the 23 patients with cardiac disease, the condition was known at the time of referral in 15 cases and was an incidental finding during preoperative investigation for abnormal electrocardiographic (ECG) findings in eight. All but two patients with ischaemic heart disease were heavy smokers.

For patients with preoperative cardiac problems, a cardiology consultation was obtained routinely. Generally, cardiac investigation for patients suspected to have ischaemic heart disease consisted of stress ECG monitoring, dipyridamole–thallium myocardial scintigraphy and echocardiography. For patients with either anteroseptal or diffuse ischaemia, coronary arteriograms were obtained to assess the extent of atherosclerosis. For patients with valvular heart disease, echocardiography was performed to assess left ventricular function.

Regular perioperative care for patients who underwent hepatic resection included fluid restriction with 30–40 ml kg^{-1} of intravenous fluid containing 5–10 per cent dextrose per day. For patients with hepatic dysfunction, sodium intake was strictly limited. For cirrhotic patients, spironolactone 200 mg was administered intravenously during the early postoperative period. For hypoalbuminaemia, 25 g salt-poor albumin was infused intravenously. Central venous pressure was measured as needed. For urine output of less than 0·5 ml kg^{-1} h^{-1} with hypovolaemia, plasma protein fraction or salt-poor albumin was infused as assessed on an hourly basis, while low urine output with an adequate intravascular volume was treated by intravenous frusemide. The nasogastric tube was removed on the first postoperative day, and oral intake was started the next day.

Pulmonary artery pressure was monitored by a Swan-Ganz catheter in six of the 23 cardiac patients: four who had had a previous myocardial infarction, one with hypertrophic non-obstructive cardiomyopathy and one after mitral valve replacement. After operation seven patients stayed in the intensive care unit for 1–9 (mean 2) days. Patients with ischaemic heart disease were given nitroglycerin intravenously or as a paste patch.

For the two patients who had had mitral valve replacement, perioperative anticoagulation coverage was with heparin, which was converted back to warfarin as soon as oral intake was resumed.

A patient with an atrioventricular pacemaker for sick sinus syndrome underwent three hepatic resections with fixation of the pacing rate during the procedure.

The perioperative details of patients with cardiac disease were compared with those of the other 428 with no preoperative cardiac disease who underwent 449 hepatic resections during the same period. Intraoperative hypotension was defined as systolic blood pressure below 80 mmHg for more than 10 min.

Statistical analysis was with the two-tailed Student's t test or the χ^2 test for data comparison; survival was analysed with the Kaplan–Meier method. Results are expressed as mean(s.d.). $P<0{\cdot}05$ was considered statistically significant.

Paper accepted 7 January 1996

Results

The annual incidence of hepatic resection for patients with preoperative cardiac conditions has been 14 (10 per cent) of 147 patients since 1992, which was significantly higher than 11 (3 per cent) of 328 before 1992 ($P < 0\cdot01$).

Patients aged 50 years or older had a significantly higher incidence of cardiac conditions compared with younger patients (25 (6 per cent) of 402 *versus* 0 of 72, $P = 0\cdot04$).

There was a higher incidence of diabetes mellitus (11 (44 per cent) of 25 *versus* 81 (18 per cent) of 449, $P < 0\cdot01$) and hypertension (13 (52 per cent) of 25 *versus* 73 (16 per cent) of 449) among patients with cardiac conditions, while other data including liver function were similar in the two groups.

Table 1 compares intraoperative data between patients with and without preoperative cardiac conditions. All variables evaluated were similar in the two groups.

Table 2 shows morbidity and mortality after hepatic resection in patients with and without preoperative cardiac conditions. The incidence of cardiac complications was significantly higher in patients with preoperative cardiac conditions than in those without. Two patients who had had a previous myocardial infarction had a postoperative infarction. Of the two patients who developed acute myocardial infarction after hepatectomy, rapid expansion of the tumour was judged to preclude preoperative coronary artery bypass surgery for three-vessel disease in one case. In the other patient, exercise ECG findings were negative, and follow-up coronary angiography with possible percutaneous transluminal coronary angioplasty (PTCA) was deemed unnecessary. One patient, 71 days after myocardial infarction and treatment with PTCA, underwent hepatic resection without recurrent infarction. Clinically significant arrhythmias occurred in two patients in each group: atrial fibrillation with tachycardia and frequent ventricular premature contractions in those with a previous cardiac condition, and atrial fibrillation with tachycardia and supraventricular tachycardia in those without.

Contrary to the marked difference in cardiac complications, the overall incidence of non-cardiac complications was similar in the two groups. Neither of the two patients anticoagulated by heparin for replaced mitral valves developed haemorrhagic complications. Liver failure and bile leaks were more frequent in those with preoperative cardiac conditions. The incidence of hospital death was markedly different between the two groups, due primarily to the higher incidence of liver failure in patients with preoperative cardiac conditions.

Table 3 lists morbidity and mortality after hepatic resection in patients with cardiac conditions. All hospital deaths were in those with ischaemic heart disease for whom the hospital death rate was four of 16 patients in spite of average incidence of postoperative complications.

Of the five patients with a previous myocardial infarction who underwent hepatic resection, two did not undergo coronary angiography before operation but did well after surgery. Another patient had undergone uncomplicated abdominal aortic aneurysmectomy and Hartmann's procedure for cancer of the sigmoid colon 13 months before hepatectomy at another hospital. After right hepatic lobectomy for liver metastasis, this patient developed intra-abdominal bleeding and required laparotomy for haemostasis. After the reoperation he developed liver failure followed by autopsy-proven acute myocardial infarction and died from multiple organ failure. Another patient had undergone PTCA after suffering from myocardial infarction 33 months before

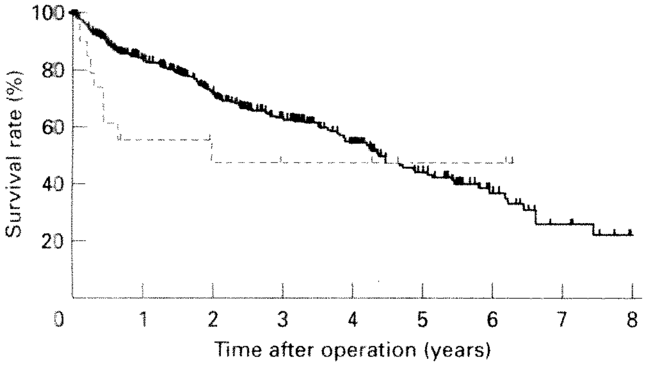

Fig. 1 Patient survival after hepatic resection. Patients with a preoperative cardiac condition (– – – –) showed a sharp decline in survival for the first 6 months after operation. Thereafter, survival was similar to that in patients with no preoperative cardiac problems (———). Overall there was no significant difference between the two groups

hepatic resection. Investigation by double master electrocardiography and stress thallium myocardial scintigraphy showed no abnormality and coronary angiography was not performed. This patient underwent right trisegmentectomy for a rapidly growing primary malignant lymphoma. He was discharged 20 days after operation but developed acute myocardial infarction 22 days later, for which PTCA was again performed. He remains alive and well. The other patient with cholangiocarcinoma was operated 71 days after myocardial infarction. Because of rapid growth of the cancer, right hepatic lobectomy was performed immediately after successful PTCA of the right coronary artery to reduce stenosis from 99 to 25 per cent, and the patient's postoperative recovery was uneventful.

Fig. 1 shows the survival of the patients with and without cardiac conditions after hepatic resection. Although the short-term survival of cardiac patients was not as good as that of non-cardiac patients, the long-term survival rate was similar in the two groups.

Discussion

Cardiac conditions known to be associated with circulatory complications after non-cardiac surgical procedures include ischaemic heart disease, preoperative arrhythmias or heart failure, aortic valvular disease and hypertrophic obstructive cardiomyopathy. Of these, previous myocardial infarction within 6 months and present congestive heart failure are regarded as the most dangerous[6,7]. Non-cardiac risk factors for cardiac complications after non-cardiac operations include age over 70 years, emergency surgery, major vascular surgery, and prolonged thoracic or upper abdominal surgery[6,7].

Measures to reduce cardiac complications include accurate assessment of cardiac conditions by various diagnostic techniques, correction of circulatory problems including preoperative control of congestive heart failure or correction of significant coronary artery stenosis by bypass surgery or PTCA before contemplated surgery and intraoperative haemodynamic monitoring with an arterial line and a pulmonary artery catheter[6–10].

As to the relevance of concomitant cardiac conditions to the outcome of hepatic resection, Stimpson *et al.*[1] in 1987 described their experience with 58 elective major hepatic resections; ECG findings were not a sensitive indicator of postoperative cardiac complications. Iwatsuki and Starzl[2] in 1988 reported that two of 411 patients developed acute myocardial infarction, of whom one died during operation. Belghiti *et al.*[10] in 1993 documented 81 patients who underwent elective hepatic resection, of whom one (1 per cent) died from a myocardial infarction that occurred 24 h after surgery. Of 90 patients aged at least 65 years who underwent elective hepatic resection, Fortner and Lincer[3] reported postoperative cardiac complications in 11 (12 per cent), consisting of arrhythmias in five (6 per cent), congestive heart failure in four (4 per cent) and acute myocardial infarction in two (2 per cent). Of two patients with postoperative myocardial infarction, one had had a previous infarction and required an emergency operation for haemobilia, and the other with a normal preoperative electrocardiogram developed a fatal infarction 12 h after surgery; autopsy revealed 90 per cent stenosis of four cardiac vessels.

For cardiac patients with malignancy, tumour growth and spread need to be weighed against the time required for cardiac investigation and correction of cardiac problems. As to the safety of non-cardiac surgical procedures after coronary revascularization procedures, Mahar *et al.*[11] reported no perioperative myocardial infarction among 99 cardiac patients who underwent 168 operations following coronary artery bypass. Crawford *et al.*[12] also demonstrated that the operative risk of patients with previous coronary artery bypass is similar to that of patients with no coronary artery disease.

Although the present authors' experience with myocardial revascularization procedures is limited, such preparations for elective hepatic resection seem important to reduce postoperative myocardial infarction among high-risk candidates[9,11,12]. Although PTCA is less invasive than coronary artery bypass, early restenosis is common: 13 per cent within 1 month and 43 per cent within 3 months in one study[13]. Therefore, we consider that coronary angiography is necessary for cardiac evaluation if PTCA has been performed more than 3 months before the prehepatectomy investigations.

The high incidence of liver failure and bile leak after elective hepatic resection for patients with concomitant cardiac conditions in the present series is noteworthy. Liver failure among cardiac patients could be attributed to postoperative intra-abdominal bleeding in one and to bile peritonitis in another, and possible excessive resection in a 70-year-old woman with hepatic cirrhosis, while the cause was undetermined in the other patient who had been on haemodialysis for chronic renal failure. To reduce early postoperative mortality and morbidity after hepatic resection, patients with cardiac conditions should undergo hepatectomy with special attention to minimizing intraoperative blood loss and haemodynamic instability, and to achieving perfect haemostasis and control of bile leaks from the raw liver surface. For cardiac patients with concomitant liver cirrhosis, non-cancerous hepatic parenchyma should be preserved as much as possible[14].

Pilonidal sinus: experience with the Karydakis flap

P. R. B. KITCHEN

Department of Surgery, St Vincent's Hospital, 41 Victoria Parade, Melbourne, Victoria 3065, Australia
Correspondence to: Mr P. R. B. Kitchen

A personal series of 141 patients with postanal pilonidal sinus was treated by the Karydakis operation. Each sinus was totally excised with a vertical eccentric elliptical excision. A thick flap was created by undercutting the medial edge and advancing it across the midline so that the whole suture line was lateralized to reduce the risk of recurrence. Follow-up was achieved in 114 patients for 1–108 months; 79 (69 per cent) were followed for more than 18 months. Overall there were five recurrences (4 per cent) which required further surgery. Thirty-three patients (23 per cent) were referred following recurrence or failure of healing after previous surgery elsewhere; all were cured by this method. The Karydakis operation has a low recurrence rate because it produces a shallow midline furrow free from scar or suture holes which is less vulnerable to hair penetration than a midline wound.

Pilonidal sinus may be treated in a number of ways. Karydakis[1] published the largest series in the literature (6545 cases) and argued for a technique that prevents recurrence as well as curing the presenting condition. The present author has used this method successfully since 1973, finding it to work especially well in difficult cases referred when other surgery has failed. This paper emphasizes some of the details of operative technique designed to ensure a successful outcome.

Patients and methods

The operation was performed on 141 consecutive patients with chronic postanal pilonidal sinus between December 1973 and February 1995. Details of some of these patients have been reported previously[2]. Mean age was 25 (range 13–64) years. Overall 70 per cent of patients were male and 45 per cent were of Mediterranean (Greek, Italian or Arabic) origin. Patients presented with discharge (47 per cent), a lump alone (20 per cent) and/or a history of previous abscess (53 per cent). Follow-up after operation was achieved in 114 patients (81 per cent) and involved personal contact with each or, if this was impractical, a telephone call made to the referring doctor. Median follow-up was 22 (range 1–108) months and 79 patients (69 per cent) were followed for more than 18 months.

Thirty-three patients (23 per cent) presented with recurrence after previous surgery by other surgeons; seven had persistently unhealed midline wounds and 18 had had previous surgery on two, three or four occasions. All sites of previous recurrence were in the midline. Four patients had inadequately lateralized scars from a previous Karydakis operation in which sinuses recurred where the scar met the midline, and three had failed Z-plasties, with openings at the lower end of the scar. One patient with an unhealed wound had a new sinus extending into the anus.

Surgical technique

An asymmetrical biconcave ('elliptical') incision is made, with the patient positioned prone and with the buttocks strapped apart. The ellipse is based on the side of any secondary opening or induration; if the sinus is entirely central, either side may be chosen. The incision is at least 5 cm long with gentle curvature. Each end of the incision is placed 2 cm to one side of the midline (*Fig. 1*). The medial edge of the excision crosses the

---

Paper accepted 21 November 1995

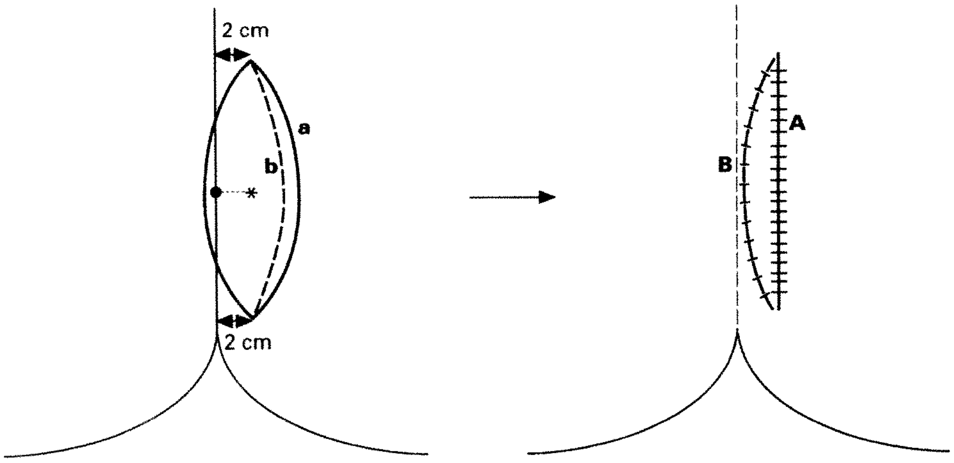

Fig. 1 Left: a biconcave incision started and centred 2 cm to one side of the midline cleft and skirting the cleft just sufficiently to excise the primary opening (●) and whole track. If there is a secondary opening (*) it may be the centre of this ellipse. If the sinus is entirely in the midline the centre could be on either side. The lateral edge (**a**) must be cut symmetrically with the medial edge. If less is excised laterally to conserve tissue (**b**) a wound will be produced (right) that tends to lie in the midline (**B**) with a higher risk of recurrence than a well lateralized wound (**A**)

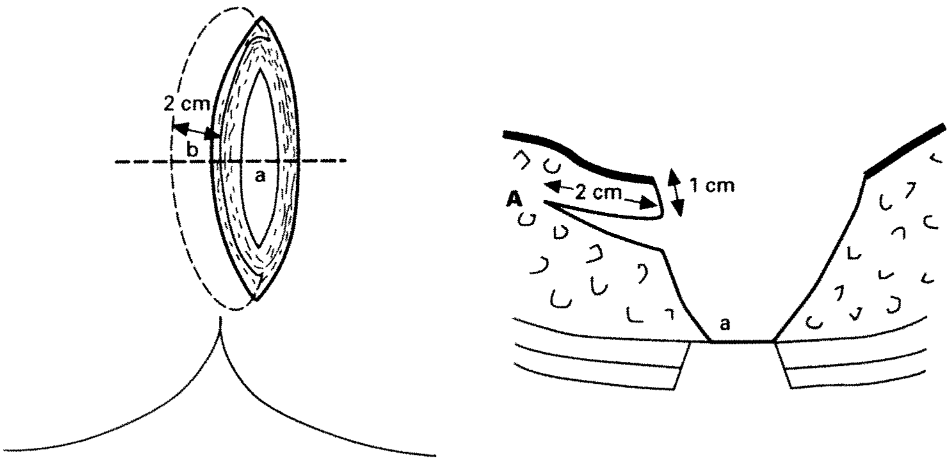

Fig. 2 On the right is a cross-section of the centre of the wound indicated on the left with a dashed line. A wedge of tissue is excised including the full sinus track down to the sacral fascia (**a**) and a lateral flap is created along the full length of the medial edge, undercutting a distance of 2 cm at a depth of 1 cm

midline sufficiently to encompass the primary pit. Probing and insertion of povidone–iodine or methylene blue helps to ascertain the extent of the sinus so that the whole sinus and its ramifications can be fully excised without inadvertent contamination of the wound by opening the track. The lateral edge of the excised ellipse must be symmetrical with the medial edge even if this means excising more skin and fat well beyond the sinus, so that the final suture line is vertical, or its central part may encroach towards the midline, which increases the risk of recurrence. The scalpel is inserted down to muscle and sacral fascia to remove a boat-shaped wedge of tissue including the whole sinus. Diathermy is not used until the tissue has been excised to avoid confusion of burn marks with methylene blue from divided sinus branches. The medial side of the wound is then undercut a distance of 2 cm at a depth of about 1 cm to produce a flap extending the full length of the wound (*Fig. 2*). The flap should be of uniform thickness. Cutting the flap may expose the deep fascia and muscle in a thin patient but will be within fat in obese patients.

A layer of interrupted absorbable sutures (1 chromic catgut or dexon) is placed before any is tied, the needle being passed into the sacral fascia in the midline and then deeply into the fat at the base of the flap, taking a large bite that includes both surfaces of the undercut (*Fig. 2, point A*). As this series of sutures is tied, the assistant can both evert the edge with fingers and use a thumb to push the base of the flap across to the midline to approximate the surfaces for knotting (*Fig. 3*). A suction drain is placed across these knots and brought out well laterally before the second layer of sutures is placed to approximate the undersurface of the flap to the fat in the lateral edge of the wound. During insertion of these sutures the assistant can evert the edge and hold knots during tying as before. A useful modification is to take an additional bite of deeper fat or fascia while placing these sutures, which helps flatten the flap and avoids a dead space (*Fig. 4*). Interrupted fine nylon sutures are placed in the skin. If the skin edge on the flap tends to invert, a further shallow cut can be made just beneath the skin of this edge to evert it and vertical mattress manner knots used where necessary. These should not be tied tightly to avoid necrosis of the skin edge. Care should be taken to leave no suture hole, drain hole or any part of the wound in the midline.

In the unusual situation where there are secondary openings on both sides of the midline, a small side-cut into the wound edge may be necessary to fully excise the track extension and opening. The wound then has a T-junction which is closed with an apical skin suture (*Fig. 5*).

One dose of intravenous antibiotic is given during the operation and a firm dressing is applied to the closed wound. A rolled pad can be used over gauze to flatten the flap and help create a new shallow midline furrow. The patient is nursed supine in the recovery room to help haemostasis by pressure. The patient is kept in bed for 2 days, to prevent haematoma formation; after this period the drain is removed and the dressing is replaced before discharge from hospital on the third

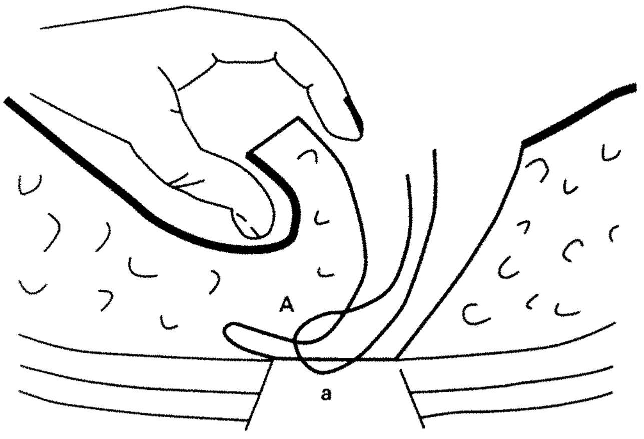

Fig. 3 The deepest sutures are all placed before any is tied, the assistant pushing the base of the flap across and everting its edge to aid tying of the knot (**A** to **a**)

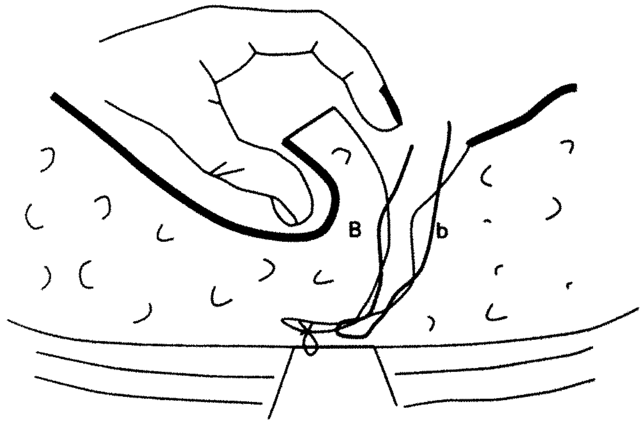

Fig. 4 The second layer of absorbable sutures apposes two surfaces (**B** to **b**) and also takes a deeper bite to avoid a dead space

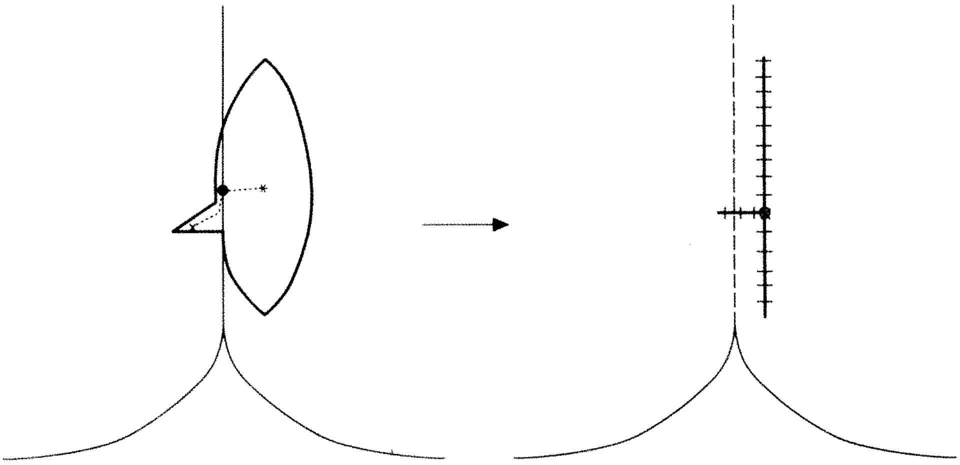

Fig. 5 When there are secondary openings on both sides, the most lateral or larger is chosen as the centre for the elliptical excision. Once the sinus is excised, a V cut is made into the other edge to excise the track and opening fully (left). The edges of this V are sewn together and brought across to the opposite surface with an apical suture to form a T-junction (right)

or fourth day. Sutures are removed after 10 days. Patients return to work in the third or fourth week. It is wise to shave the wound and around it twice weekly for a month, but this can then cease.

Results

Mean length of hospital stay was 4 days and most patients returned to work within 4 weeks. Immediate postoperative complications were haematoma in seven patients and wound infection in six. Late complications were some wound numbness in 17 patients (12 per cent) and slow healing in four (3 per cent). There were five known recurrences (4 per cent) from 9 to 18 months after operation; all were in the midline. Four recurrences occurred in the first half of the series in cases where the wound encroached on to the midline. One was a new sinus in the new midline furrow. They were cured by curettage (two patients), laying open (one) or a second Karydakis procedure (two). All 33 patients who presented with recurrence (26) or failure of healing (seven) after previous surgery were dealt with successfully by the Karydakis method. Some of these required large eccentric excisions producing well lateralized wounds. Only one of these has developed a further recurrence which was small and was cured by curettage.

Discussion

A major cause of pilonidal sinus is insertion of loose hairs that collect in the gluteal furrow. This tendency is aggravated in individuals with a deep cleft or a portal for hair entry in the midline[3]. Good postoperative advice is to rub the furrow daily with a rough towel after bathing to remove loose hairs, but indefinite shaving of the buttocks or use of depilatory creams will only set up irritation and is unnecessary since the cause of the sinus is gathered loose hairs entering by their roots[2], not hairs growing in the buttock skin[4]. Most operations can cure the sinus but risk development of recurrence, either in the short term (failed wound healing) or long term (new sinus development[5]). Early recurrence may be due to the presence of a wound in the midline acting as a portal for hair entry, and later recurrence may occur because of a deep furrow, in which loose hairs may collect. Surgery should not only eradicate the presenting sinus but should also aim to eliminate factors that predispose to formation of another sinus. This is achieved by reducing the depth of the cleft and ensuring that all parts of the wound and all suture holes are away from the midline. Bascom's cleft closure operation[6] produces a lateral wound and the Z-plasty procedure[7] and V-Y fasciocutaneous flap[8] reduce the depth of the natal cleft and hence have low recurrence rates[9]. However in the present series there were three patients who presented with recurrence after previous Z-plasty when new sinuses occurred at the lower end in the midline where the wound meets the midline and the cleft is not flattened.

The aim in all surgery should be to minimize both the financial cost to the community (treatment efficiency) and the cost to the patient in terms of time off work, number of dressings and postoperative visits, complications and recurrences (treatment effectiveness). Allen-Mersh[9] in 1990 extensively surveyed the literature on various operations and their results. Karydakis[1] reports the largest patient numbers and has a very low recurrence rate (1 per cent) at 2 years or more. Some series have shorter follow-up, which means their recurrence rates may be underestimates[5]. Excision with an open wound involves prolonged hospitalization or clinic attendance for many painful dressings and takes months to heal. Both that method and excision with marsupialization leave a portal in the midline for further hair entry and have a small but significant recurrence rate[9-14]. Several series have shown that excision with primary closure is preferable to excision with an open wound in many respects: less bleeding, less wound breakdown, lower infection rate, reduced wound pain, fewer postoperative visits, shorter time off work and faster healing time[11,13,15]. These advantages outweigh any increase in recurrence rate.

Day surgery with simple laying open, curettage, brushing or phenol injection may get rid of the hairs and cure the sinus but the midline wound may take several weeks to heal and there is a significant recurrence rate because of the open portal for hair insertion[9]. Thus the advantages of simple day surgery may be outweighed by the longer time to return to work and the greater likelihood of a further operation with longer hospitalization for recurrence. Asymmetric excision with a Karydakis flap is the only operation that takes the whole wound away from the midline. It is easy to learn and teach, and this study confirms that it has a very low recurrence rate, fast healing time and short period off work.

Acknowledgements

The author wishes to acknowledge the work of the late Dr George Karydakis, whose extensive experience and excellent results stimulated his interest in this approach to pilonidal sinus.

Brush cytology for the diagnosis of rectal carcinoma

R. FAROUK, J. EDWARDS*, M. THORNE, W. YOUNG*, A. W. MACDONALD, J. R. T. MONSON and P. W. R. LEE

*Academic Surgical Unit, University of Hull and *Department of Pathology, Castle Hill Hospital, Castle Road, Cottingham, Hull HU16 5JQ, UK*

Correspondence to: Professor J. R. T. Monson

The use of brush cytology as an aid in the preoperative diagnosis of rectal cancer was prospectively assessed at 328 examinations in 289 consecutive patients with rectal lesions suspicious of carcinoma. Forty-five patients were reported as having benign polyps. There was 97 per cent agreement between conventional biopsy and cytology brushings for this group. Some 249 patients underwent a subsequent resection allowing comparison with formal histology. Forceps biopsy produced a true-positive diagnosis of cancer in 218 patients (89·7 per cent) and cytology in 222 (91 per cent). The sensitivity for forceps biopsy and cytology was 81 and 83 per cent respectively, with a combined sensitivity of 98 per cent. It is concluded that the addition of cytology to forceps biopsy increases the diagnostic yield in a single examination, and may be a complementary method of establishing the diagnosis of rectal lesions.

Where there is clinical suspicion of a rectal carcinoma, it is mandatory to obtain histological diagnosis before treatment. Histological confirmation of the diagnosis is conventionally achieved by forceps biopsy. Finger-guided biopsy may be used for very low rectal lesions[1]. Forceps biopsy is occasionally difficult because of the anatomical site of the tumour, or because the tumour is obscured by bowel content or blood-stained mucus, or both. Occasionally, the lesion encountered is widespread, raising the difficulty of perhaps missing a malignant area in a very large adenoma. Apart from the complications of perforation and haemorrhage, biopsy may be inconclusive because of unsatisfactory samples. The patient's management is therefore delayed while re-examination for further biopsy specimens is undertaken. The use of brush cytology in the diagnosis of colorectal malignancy and to determine the aetiology of colonic strictures has previously been demonstrated to be feasible[2–6]. The aim of this study was to assess brush cytology as an aid for the diagnosis of rectal cancer.

Patients and methods

A total of 289 consecutive patients seen at a rectal outpatient clinic, over a 3-year period, with rectal lesions suspicious of carcinoma were studied prospectively. Each patient underwent a full anorectal examination, and the lesion was then brush biopsied with a Cytotec (Cell Path, Hemel Hempstead, UK) cervical smear brush. The brush was rubbed and turned against the lesion directly, or via a sigmoidoscope. The brush head was then placed in cytological fixative solution and transported to the pathology laboratory where the cytologist prepared the slides. A conventional forceps biopsy of the lesion was then performed. If the latter biopsy yielded a negative result, the patient was re-examined, and repeat brushings and biopsy specimens were obtained. Some 249 patients subsequently underwent surgical resection, allowing the final diagnosis to be established by means of histological examination of the resected specimen.

Results

The results obtained by forceps biopsy were reported as either positive or negative for carcinoma. Cytological interpretations of the brushings were expressed as positive for (grade C5), or suspicious of (C4), carcinoma, benign

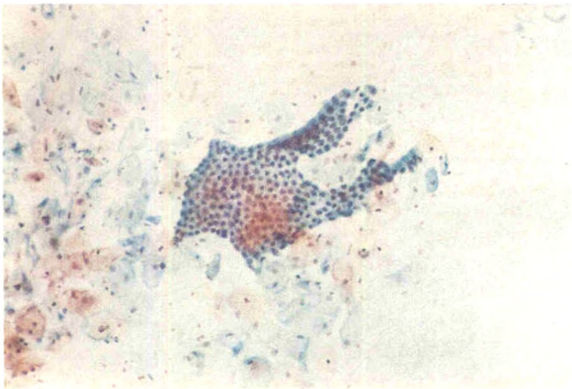

Fig. 1 Malignant cells on brush cytology. Note the large pleomorphic nuclei, with minimal clumping of cells. (Haematoxylin and eosin stain, magnification ×25)

Presented to the Association of Coloproctologists of Great Britain and Ireland in Cork, Ireland, July 1995
Paper accepted 10 December 1995

Table 1 Summary comparing results from forceps biopsy and cytology brushings for the diagnosis of rectal carcinoma

	Forceps biopsy	Cytology brushings
True positive (*n* = 244)	215 (88·1)	221 (90·6)
True negative (*n* = 45)	45 (100)	44 (97·8)
False positive (*n* = 289)	0 (0)	1 (0·005)
False negative (*n* = 244)	34 (13·9)	23 (9·4)

Values in parentheses are percentages

(C2), or insufficient for diagnosis. Cytological diagnosis of malignancy was made on the basis of poorly cohesive cells with large, darkly staining nuclei (*Fig. 1*). Benign brushings were identified as large groups of cells showing cohesion, with normal nucleus:cytoplasm ratios (*Fig. 2*).

Thirty-nine patients (13·5 per cent) with a negative result from the initial forceps biopsy, but who had a cytology brushing report suspicious of malignancy required re-examination with further biopsy and brushing. The initial biopsy and brushings result for these patients, and not the repeat examination outcome, have been used for subsequent analysis.

Four patients had inadequate cytological brushings for reporting but had positive forceps biopsy results. Forty-one patients were found to have benign polyps, all of which were correctly identified by forceps biopsy and 40 by cytological brushings. The final histological diagnosis of the resected specimens showed that 244 of the 249 patients undergoing surgical resection had an adenocarcinoma of the rectum. Five patients had villous adenomas with a high degree of dysplasia but without carcinomatous change (*Table 1*).

A true-positive diagnosis of cancer was made by cytology in 207 patients (84·8 per cent). A further 14 patients (5·7 per cent) were regarded as suspicious for malignancy. There were 23 false-negative reports (9·4 per cent), nine of which were for 'atypical' tumours: anaplastic carcinoma of the rectum (three patients), squamous carcinoma of the rectum (one), metastatic oat-cell bronchial carcinoma (one) and squamous carcinoma of the anus encroaching upon the rectum (four).

Forceps biopsy produced 215 (88·1 per cent) reports of a true-positive carcinoma of the rectum, while there were 34 (13·9 per cent) false-negative diagnoses. There was agreement between cytology (positive and suspicious reports) and forceps biopsy on a positive result in 216 cases (88·5 per cent). The sensitivity for cytology and forceps biopsy was 83 and 81 per cent respectively, with a combined sensitivity of 98 per cent. The specificity of cytology and forceps biopsy was 90 and 100 per cent respectively.

The five patients who underwent anterior resection for a villous adenoma did so because of the high degree of dysplasia, and the extensive nature of these lesions. These five patients were correctly identified as showing no evidence of malignancy by forceps biopsy. Cytology correctly diagnosed four of these five patients as being negative for malignancy, but in the remaining patient provided a diagnosis of suspicious for malignancy.

Discussion

Cytological diagnosis of rectal cancer was first described as a case report by MacKenzie and Hechte in 1948[7]. The use of a brush for exfoliative cytological diagnosis of colorectal lesions was first advocated by Ayre and Oren[3]. The application of digital scrape cytology was subsequently described[1]. The histological confirmation of rectal cancer, however, remains mainly confined to the use of forceps biopsy via a sigmoidoscope. Such a technique allows unequivocal evidence of submucosal invasion indicative of malignancy. Cytological diagnosis is based on cell morphology and cannot give information on architectural evidence of invasion[8]. An endoscopic finding of an ulcerated or annular lesion is unlikely to be an adenomatous polyp, however, and the finding of cytologically malignant cells from the brushings of such a lesion can therefore be safely interpreted as indicative of a carcinoma.

In this report, cytology incorrectly diagnosed one of five villous adenomas that were resected to be suspicious for malignancy. This reflects previous findings that the surface of adenomas may contain dysplastic or even malignant cells without evidence of invasion[8]. While the five patients underwent subsequent resection because of the extensive nature of these polyps, it emphasizes the need for caution in the cytological interpretation of polypoid lesions. There were also 23 false-negative reports based on cytology. In nine of these patients, there was a failure of interpretation because of the atypical nature of the tumour. This contrasts with previous reports which suggest that it is a failure of the sampling process rather than a misinterpretation that results in false-negative reports[2,6]. Such false-negative sampling was also seen in 34 patients who were biopsied and not reported to have a tumour, although cytology brushings were malignant. Re-examination and biopsy confirmed the presence of tumour in these patients. The false-positive rate of cytology brushings from this series is therefore 0·3 per cent (one in 289 patients) with a false-negative rate of 9·4 per cent. These rates are favourable compared with those for cytological diagnosis of breast cancer[9,10].

The sensitivity of the cytology brushings was comparable with that of forceps biopsy (84 *versus* 81 per cent respectively). When the two methods are combined, the sensitivity improved to 98 per cent. This increase in diagnostic yield compares with that observed from smaller series. Cytology has previously been shown to have a sensitivity of 82 per cent compared with 80 per cent for forceps biopsy in a series of 130 patients with primary colorectal carcinoma[5]. The combined sensitivity of the two methods was 97 per cent in this study. In a separate study, Bemvenuti *et al.*[4] reported the results of 202 brushings, 23 of which were from carcinomas. Cytology brushings correctly identified malignancy in 18 patients (82 per cent). Among the 179 benign lesions in this series, there were no cytological false positives, with 174 reports being correct. In addition, Mortensen *et al.*[6] have described the results of colonoscopic brushings from 79 patients with strictures. Brush cytology was shown to be considerably more accurate (81 per cent) than endoscopic biopsy (61 per cent) in the diagnosis of the aetiology of colonic strictures.

At present brush cytology appears to be best suited as a complementary investigation to forceps biopsy given its limitations with polypoidal lesions, and a definite false-negative rate. It is a quick, simple and complication-free manoeuvre that can increase diagnostic yield. Brush cytology can provide important confirmation of malignancy, and may prevent the need for re-examination.

Surgical workshop

Subcutaneous bridge support for defunctioning loop colostomy

S. W. ATKINSON and P. G. BENTLEY

Department of Surgery, Kent and Sussex Hospital, Mount Ephraim,
Tunbridge Wells TN4 8AT, UK
Correspondence to: Mr P. G. Bentley

It is conventional to support a loop colostomy for a number of days after it has been fashioned to prevent retraction into the abdomen. This manoeuvre is usually accomplished by a plastic 'bridge' overlying the incision used to create the stoma. This technique has the disadvantage of not only preventing complete mucosa-to-skin apposition but also causing difficulties in fitting an appliance to encircle the stoma accurately. A modification of this common procedure that obviates these difficulties is described.

Surgical technique

The colon is exteriorized, and a defect for the stoma is created in the anterior abdominal wall in the standard fashion. Incisions (5 mm) are made in the skin in a transverse direction to the normal orientation of the colon, 5 cm from the stoma. A Jacques catheter or nasogastric tube is passed subcutaneously from one incision, behind the colon to be exteriorized, and again subcutaneously to exit from the other incision (*Fig. 1*). The colon is opened and sutured to the skin, and an appliance is fitted. The subcutaneous bridge is secured at either end with a suture and cut short to allow enough for subsequent removal after 5–7 days.

Paper accepted 18 December 1995

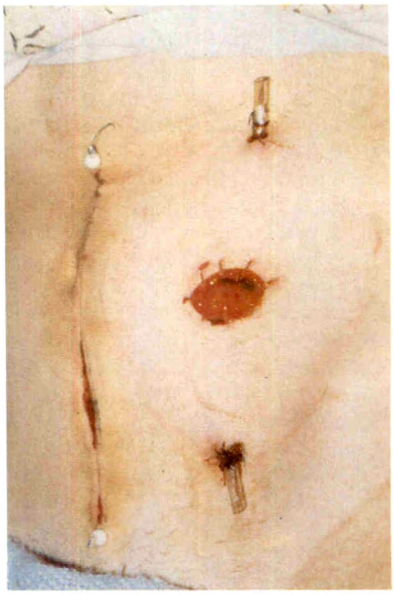

Fig. 1 Position of the Jacques catheter or nasogastric tube in a patient undergoing a loop colostomy

Discussion

The new method allows complete integrity of the mucocutaneous junction from the time of the creation of the stoma, thus preventing contamination of the peristomal subcutaneous tissue. It also permits positioning of an appliance flush with the stoma, making excoriation of the skin and leakage from the appliance less likely. The authors recommend the method for its aesthetic and practical appeal.

Effect of different infusion regimens on colonic motility and efficacy of colostomy irrigation

J. M. GATTUSO, M. A. KAMM, C. MYERS, B. SAUNDERS and A. ROY

St Mark's Hospital, Northwick Park, Watford Road, Harrow HA1 3JU, UK
Correspondence to. Dr M. A. Kamm

The colonic motility response and short-term clinical effectiveness of colonic irrigation was studied in five patients with an end-colostomy, each of whom was studied on up to six occasions, using volumes of 500 and 1500 ml water infused under gravity and over a period of 2·5 and 5 min with a pump. The median baseline colonic luminal pressure was 14 cmH_2O and rose to 42 cmH_2O with a 500-ml infusion, and to 74 cmH_2O with a 1500-ml infusion. Irrigation induced high-pressure (over 200 cmH_2O) propagated waves which caused the efflux of colonic contents. These were more numerous after a 1500- than a 500-ml infusion (median 4·5 *versus* 2·0 respectively). There was no difference between the two volumes infused in the incidence of colostomy breakthrough before subsequent irrigation. Colostomy irrigation with 500–1500 ml water appears to produce intracolonic pressure rises that are safe. These volumes can be infused rapidly under gravity alone.

A colostomy is managed by one of the following: (1) natural spontaneous evacuation; (2) control of the colostomy output by drugs; and (3) colostomy irrigation[1]. The first two regimens lack good continence control, may require the use of a bulky appliance, and may produce a faecal odour. Colostomy irrigation is gaining in popularity as the safety of modern methods and the ability of even elderly patients to cope with the technique is recognized[2–4].

A major disadvantage is the time needed to perform irrigation, usually up to 1 h every 1–2 days. There is also little information regarding the ideal volume to be infused[5], and no information on the effect of the rate of inflow on the outcome of irrigation. These factors may be critical in obtaining the maximum benefit from irrigation.

The aims of this study were to determine (1) whether a large volume of fluid infusion produces a better result than a small volume infusion; (2) whether the infusion rate of the fluid is important in achieving a good result; (3) whether a pump is necessary to achieve rapid infusion, and whether this is beneficial and safe; (4) the intracolonic pressures during infusion at different volumes and rates; and (5) the relationship between the intracolonic pressures during colostomy irrigation and the outcome and occurrence of side-effects such as pain.

Patients and methods

Five patients (two women) of mean age 63 (range 59–66) years were studied. One patient (no. 1) had long-standing constipation (bowel action every 4–5 days) before operation; the rest had a pre-stoma bowel frequency of once per day. The patients had no other gastrointestinal problems. All had undergone abdomino-perineal resection with formation of an end-colostomy for rectal adenocarcinoma and were using irrigation as the preferred method of colostomy management. Patient details are shown in *Table 1*. The time spent performing colostomy irrigation was variable, but usually took up to 1 h, including 'cleaning up'. Three patients had difficulty with excessive flatus and four had occasional minor soiling, both occurring during the few hours before irrigation. Four patients graded the effectiveness of their usual irrigation technique as good or excellent, and one patient (no. 2) as fair to good. No patient was taking laxatives or other medication that affects gastrointestinal function significantly.

Table 1 Patient details

Patient no.	Age (years)	Sex	Usual volume (ml)	Interval between irrigations (h)	Break-through*
1	65	F	750–1500	48	None
2	64	M	1500	48	Once per week
3	62	M	650	24	Occasional
4	66	M	1500	48	Occasional
5	59	F	800	24	Yes (minor)

*Breakthrough was defined as any faecal discharge from the stoma between usual irrigations

Patients were studied when they would normally irrigate; in two patients this was 24 h and in three 48 h after the last irrigation. Patients had a light breakfast 4 h before the study, but there were no other dietary exclusions and no bowel preparation was used.

Colonoscopy was undertaken at 10.00 hours on each study day on unprepared bowel, without sedation. A guidewire was passed under direct colonoscopic vision into the proximal colon via the stoma. An ambulatory recording catheter (Gaeltec Ambulatory Recording System; Gaeltec, Dunvegan, Isle of Skye, UK) with three pressure transducers 10 cm apart was passed over the guidewire to lie 30–40 cm proximal to the stoma. The position of the catheter was confirmed by radiological screening after catheter placement and at the end of each study.

Recording of colonic pressures started once correct siting of the pressure transducers had been confirmed. Recording was undertaken: (1) for 30 min 'at rest'; (2) during a study meal of a sandwich and coffee, which was consumed within 20 min; (3) for 30 min after the meal; (4) during infusion of the irrigation water; and (5) for 60 min after the infusion.

After the post-meal period, a standard colostomy irrigation cone of the Laird type (Dansac, Fredensborg, Denmark) was inserted, and bags and tubing connected. Tap water at 37°C was run in under gravity, at the patient's head height, or using the pump.

Baseline pressures were measured during each component of the study. High-pressure contractile activity was also assessed, with high-pressure propagated waves being defined as a pressure rise above the baseline of more than 50 cmH_2O, involving two or more sensors, and progressing distally.

Paper accepted 12 January 1996

The postinfusion period was 'divided' into six 10-min periods. The output from the stoma was collected and measured during each of these periods.

The study was designed to investigate each subject on six separate study days. These involved: (1) 500 ml infused by gravity alone; (2) 500 ml infused over 5 min with a pump (Masterflex Pump Controller, model 7518-00; Barnant, Barrington, Illinois, USA); (3) 500 ml infused over 2·5 min by pump; (4) 1500 ml infused by gravity alone; (5) 1500 ml infused over 5 min by pump; and (6) 1500 ml infused over 2·5 min by pump If a particular volume of fluid entered the bowel in less than 5 min under gravity alone, then the 5-min pump infusion was not performed for that volume; the same procedure was adopted for the 2·5-min infusions.

After each study the patients returned home, but were asked to record any 'breakthrough' discharge of colonic contents before the next planned irrigation, in order to provide some guide as to the clinical effectiveness of each speed and volume of irrigation.

The study was approved by the Barts Hospital NHS Group Ethics Committee and all patients gave informed consent for each session.

Results

Colonoscopy and siting of recording catheter

All five patients completed the protocol, resulting in a total of 18 studies. At colonoscopy the colon contained formed stool in all patients. Colonoscopy was achieved without complication. The catheter was sited as proximally as possible, usually with the proximal tip in the transverse colon or splenic flexure and the distal pressure transducer at least 15 cm from the stoma. No significant catheter movement occurred in 14 studies as assessed radiographically. In four studies the distal transducer was extruded during the study, although the proximal two sensors remained in the colon.

Infusion of irrigate

Difficulty was experienced in initiating flow of the irrigate into the colon in some studies because of the anatomy of the stoma rather than colonic contraction. Once the infusion started, the rate of flow was always rapid. Times of infusion were recorded from when the flow started.

Using gravity alone, 500 ml was infused in a median of 2 (range 2–6) min and 1500 ml in a median of 5 (range 3–8) min.

All patients had an infusion of 500 and 1500 ml under gravity alone. Patients who had a slow infusion for a particular volume using gravity alone then had studies performed for that volume with the pump.

Pressure activity in the colon

Fig. 1 illustrates a typical manometric recording obtained during the studies. In all patients in all studies the baseline pressures did not change between the first three phases of the study: at rest, during and after the meal. The median baseline pressure of the five patients was 17 (range 3–50) cmH_2O.

In four of the 18 studies high-pressure propagated waves occurred during the preinfusion phases (*Fig. 2*).

After commencing the infusions the baseline colonic pressures increased, as shown in *Figs 3* and *4*. The increase in baseline pressure was not linearly related to either the volume infused or the rate of infusion. The median baseline pressure immediately before infusion was 14 (range 0–34) cmH_2O and rose to a median peak of 42 (range 14–101) cmH_2O with the 500-ml infusion and 74 (range 18–126) cmH_2O with the 1500-ml infusion.

The median change in baseline pressure after a 500-ml infusion under gravity was 11 (range 8–64) cmH_2O and that after a 1500-ml infusion under gravity 33 (range 11–102) cmH_2O. The pump was used to infuse 500 ml in 5 min in two patients, with pressure rises of 21 and 69 cmH_2O. In the same two patients the pump was used to infuse 500 ml in 2·5 min, with pressure rises of 12 and 63 cmH_2O. The pump was used to infuse 1500 ml in 5 min in two patients, with pressure rises of 42 and 139 cmH_2O. In two patients pressure rises of 37 and 68 cmH_2O occurred with a 2·5-min pump infusion. One 1500-ml pump infusion was terminated after 1300 ml because of abdominal discomfort. In this patient the peak pressure in the proximal transducer was 87 cmH_2O, an increase of 68 cmH_2O.

At the end of the infusion the cone was removed. There was usually an intermediate discharge of liquid followed by a number of effluent boluses containing solid and semi-formed faeces. These boluses occurred in association with recorded high-pressure propagated waves, as shown in *Fig. 5*. These high-pressure propagated waves often reached peaks of more than 200 cmH_2O. Occasional recorded high-pressure waves were not associated with any stoma output. *Table 2* shows the number of high-pressure propagated waves in each patient before and after infusion. The values for 'preinfusion' include a minimum

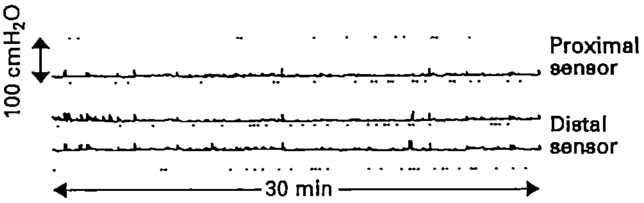

Fig. 1 Typical baseline pressure recording over a 30-min period Only a small amount of non-propagated segmenting activity is seen

41–50	0:0	0:2	0:0	0:0	0:0
51–60	0:0	0·0	0:1	0.0	0:0

*Data available for only two studies in this patient because of equipment failure

recording of 1·5 h; the postinfusion values are per 10-min period. The 1500-ml infusions were associated with a greater number of high-pressure propagated waves than 500-ml infusions (median 4·5 (range 3–8) *versus* 2·0 (range 1–9) respectively, $P = 0{\cdot}06$) but this did not reach statistical significance.

The baseline colonic pressure returned to preinfusion levels after the infusion was completed. This usually occurred within the first 10 min, and in all cases after 1 h.

Clinical effectiveness

No patient had any complications from the study. Subjectively patients considered that the 500-ml volume was not as successful as their usual volume or the 1500-ml infusion, although it was not practical to measure the actual amount of stool produced by irrigation. The output of irrigation fluid was measured, however, and was almost always found to be complete with either volume.

Discussion

Irrigation is a safe and effective method of colostomy management[2–4,6–9]. Perforation[10–15] is now rare as the irrigating cone[16] is used widely and complications such as burns[17,18] and subsequent stricture formation are avoidable.

The baseline colonic intraluminal pressures obtained in this study were similar to those reported elsewhere[19,20]. The light study meal did not induce any significant change in colonic pressures, reflecting the low calorific value of the meal[21]. The high-amplitude propagated waves have also been documented previously, both in anatomically normal colon[22,23] and in patients with a colostomy[24] in whom the introduction of the stimulant bisacodyl into the stoma produced progressive peristaltic activity similar to that observed with the introduction of water. These high-pressure events appear to be the manometric equivalent of radiographically observed mass movements. In the normal colon they occur approximately four to six times in 24 h[22,23]. After irrigation they were induced almost immediately, were most common in the first 10–20 min, and were associated with the effective evacuation of colonic contents.

Water infusion increased the basal colonic pressure. The pressure rise was greater with larger volumes, but was not greatly increased with a faster speed of infusion. Because the range of variables studied is likely to embrace the range of volumes and infusion speeds of everyday life, it is concluded that these speeds of infusion and volumes are safe.

This study has demonstrated that 1500 ml of infusate tends to result in a subjectively more effective 'irrigation' than 500 ml. In a study comparing the effectiveness of irrigation volumes 250, 500 and 1000 ml, 500 ml was preferred by the majority of patients. Objective parameters were similar, except for an increased incidence of faecal breakthrough with 250 ml[5].

The rate of infusion is usually easily adjustable with gravity alone, and this study suggests that there is no benefit from the use of a pump.

There are occasions when even experienced irrigators fail to obtain a satisfactory result from their usual irrigation technique. These data show that colostomy irrigation appears to work by the induction of high-pressure propagated waves. Further studies involving the addition of a stimulant to the irrigation fluid to achieve this may be useful[25–27]. Colostomy irrigation using 500–1500 ml can usually be achieved easily without the need for a pump.

There are no objective data available on the relative strengths of inguinal hernia repairs. The aim of this randomized controlled study was to measure the force required to disrupt laparoscopic and open mesh repairs in a porcine model. Eleven pigs had inguinal hernia repair following randomization to an open mesh group ($n = 5$) or a transabdominal preperitoneal laparoscopic group ($n = 6$). Four weeks after operation the pigs were killed and the pelvic girdles were mounted in a test jig on a mechanical testing machine. The applied disruption forces were measured and recorded. Mean(s.d.) force required to disrupt the normal inguinal canal ($n = 11$) was 68·6(30·1) N with no difference between groups. The open mesh repair required 110·3(41·4) N and the laparoscopic mesh 220·0(95·2) N. Both open and laparoscopic mesh repairs were stronger than the normal side ($P < 0·03$). The laparoscopic mesh repair was stronger than the open mesh repair ($P = 0·04$). This model provides a standardized method for mechanically testing inguinal hernia repairs in pigs. It confirms that both open and laparoscopic mesh hernia repairs are stronger than the non-herniated normal side at 4 weeks after operation. Laparoscopic mesh repair is stronger than open mesh repair. The weakest points of the repairs correlate well with those identified in clinical reports.

Inguinal hernia repair is the most commonly performed elective general surgical operation in the UK; it is estimated that 80 000 repairs are performed each year in England alone[1]. There is no consensus as to the optimal method of repair[2–5], and the recent advent of laparoscopic hernia repair has heightened the controversy[6,7]. The main problem with any type of repair is the recurrence rate, which is estimated as up to 20 per cent[8,9], and at present this is the parameter by which the long-term success of any repair is gauged.

The reasons why a repair fails are not clear; surgical technique[2], suture material[10], suture-line tension[11] and collagen abnormalities[12] have been implicated. The success of different repairs may be a consequence of a biomechanical advantage of one method over another but, in spite of the fact that inguinal hernia repair has been practised for almost two millennia[13], there has been little scientific evaluation of different inguinal hernia repairs. Recent controlled studies have attempted to address this issue but to date have reported only short-term outcomes[4,5,14]. Basic information, such as the strength of a particular hernia repair, is not available and hence the choice of hernia repair in the clinical setting has little scientific basis.

Laparoscopic inguinal hernia repair has been developed since the early 1990s[15]. The most commonly used technique at present is the transabdominal preperitoneal approach[16]. The open mesh repair has been recommended by some enthusiasts since the early 1960s[17] and it has now become more widely accepted[18]. The published recurrence rates and complications suggest it is a safe and effective method of hernia repair[19].

The authors hypothesized that the strength of a hernia repair may relate to subsequent recurrence rate. The present study compares the tensile strength of open and laparoscopic mesh inguinal hernia repair.

Paper accepted 31 May 1996

Materials and methods

All procedures were performed under the guidelines of the Animals (Scientific Procedures) Act 1986. Male pigs, each with a unilateral congenital indirect inguinal hernia (*Fig. 1*), were fasted overnight and premedicated with azaperone 0·1 ml/kg intramuscularly. An intravenous line was then inserted in the ear. Ketamine hydrochloride 5 mg/kg was used to induce anaesthesia. Following application of lignocaine spray to the larynx a size 5–7 cuffed endotracheal tube was inserted. The pigs were placed on a warming blanket and diathermy pad. The hindquarters were elevated on a wedge cushion to an angle of 25°. A pulse oximeter was connected to either the tail stump or the tongue and a rectal temperature probe was inserted. Anaesthesia using halothane, nitrous oxide and oxygen was given via a standard anaesthetic circuit. The abdomen and groin area were washed with chlorhexidine gluconate and two applications of povidone iodine. The area was then draped.

Experimental protocols

Each pig was randomized on the day of operation to either open or laparoscopic inguinal hernia repair. Five pigs were assigned to

Fig. 1 Post-mortem view of a left indirect inguinal hernia in the pig

the open group and six to the laparoscopic group. All operations were carried out by a single surgeon experienced in both techniques.

Open mesh repair. The contents of the hernia were reduced The anterior superior iliac spine (ASIS) and the pubic tubercle were identified. An incision of approximately 5 cm was made through skin and subcutaneous tissue to expose the external oblique muscle and the external ring. The external oblique was divided in the line of its fibres to expose the cord structures as far laterally as the deep ring. Care was taken to maintain haemostasis and to avoid damage to the ilioinguinal nerve. The cremasteric muscle was divided completely at the level of the deep ring. The hernial sac was identified, opened and transected. The vas and testicular vessels were dissected clear when possible The neck of the sac was then ligated in purse-string fashion. The distal portion of the sac was not excised. A polypropylene mesh was inserted, extending from just medial to the pubic tubercle to 2 cm lateral to the deep ring. It extended superiorly to 2 cm above the deep ring. The mesh was sutured to the inguinal ligament from medial to the pubic tubercle, with a 2/0 polypropylene suture running laterally towards the ASIS The mesh was secured with four interrupted sutures along the medial and superior sides. A slit in the lateral edge of the mesh allowed the cord structures to pass through. The resultant 'fishtail' was tacked with a single suture. A long-acting local anaesthetic, 10 ml bupivacaine hydrochloride 0·5 per cent, was administered close to the ilioinguinal nerve, the pubic tubercle and subcutaneously The external oblique was closed with a continuous 2/0 polyglactin suture. The subcutaneous tissues were approximated with two or three subcutaneous polyglactin stitches and the skin was closed with interrupted 3/0 polypropylene.

Laparoscopic inguinal hernia repair. A carbon dioxide pneumoperitoneum was established using a Veress needle via a supraumbilical stab wound. A 10-mm port (Ethicon Endo-Surgery, Edinburgh, UK) was then inserted through the same wound and the videotelescope was inserted. A 11–12-mm port and a 5-mm port were introduced under direct vision. They were inserted 6 cm to each side of the umbilicus using the Z technique[20]. All ports used were disposable. Any contents within the hernia were reduced. Anatomical landmarks were located. The peritoneum lining the hernial sac was incised in elliptical fashion using a scissors and graspers (Ethicon Endo-Surgery). The incision was extended both medially to the pubic tubercle and laterally toward the ASIS. Two peritoneal flaps were developed – one superiorly, one inferiorly – allowing space for the mesh. Haemostasis was continuously checked and care was taken not to damage the flaps. A polypropylene mesh was inserted via the 11–12-mm port and placed in position so that it extended from the pubic symphysis to the ASIS and covered the internal inguinal ring and the femoral area. It was kept in position with six staples. No staples were used on the inferior margin over the area occupied by the iliac and testicular vessels and the vas deferens. On the superior margin care was taken to avoid the inferior epigastric vessels. No staples were placed on the lateral side or within 1·5 cm of the ASIS to avoid injury to the lateral cutaneous nerve of the thigh. The edges of the peritoneum were then approximated and closed with staples Haemostasis was confirmed and the operating ports were removed under direct vision to ensure there was no bleeding. The telescope was withdrawn halfway out of the umbilical trocar and the trocar itself withdrawn slowly to check for bleeding or herniation. The 10-mm and 11–12-mm port sites were closed with 2/0 polypropylene. Bupivacaine hydrochloride (0·5 per cent, 10 ml) was injected into the wounds.

The skin was closed with interrupted 2/0 polypropylene sutures. The pigs were then kept in the recovery unit until they were fully mobile and drinking, which took less than 60 min for each animal. Over the subsequent 4 weeks the pigs were observed for hernia recurrence and local wound complications. After 4 weeks the pigs were premedicated with azaperone and a lethal 30-ml dose of pentobarbitone sodium 200 mg/ml was administered intravenously. At autopsy the pelvic girdle with lower abdominal wall was removed intact.

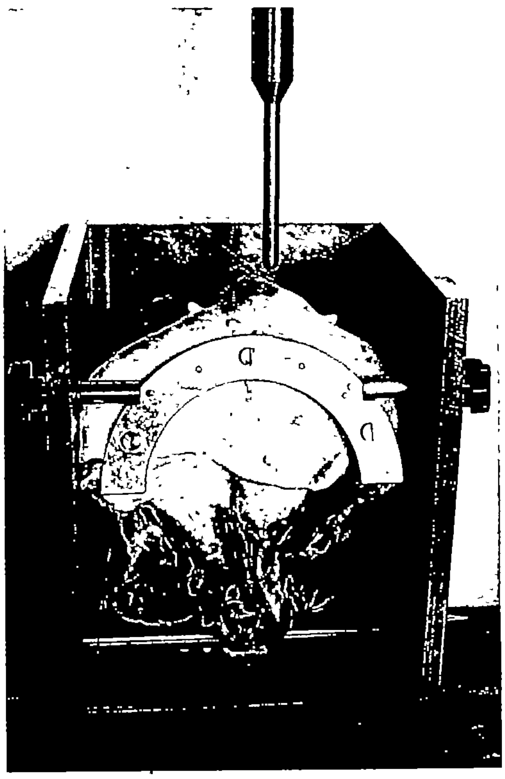

Fig. 2 Pig pelvis mounted in testing jig with rod in place before testing

Mechanical testing

The repairs were tested within 2 h of death. A three-point aluminium alloy fixator jig was developed to allow stable mounting of pelvises from pigs weighing up to 50 kg. The prepared pelvis was mounted in the jig by rigidly fixing the lumbar spine and sacrum and clamping the anterior abdominal wall at a preset tension of 200 N (*Fig. 2*). The mounted pelvis was positioned within a screwdriver mechanical testing machine (Model 6025; Instron, High Wycombe, UK).

Each repair was disrupted using a metal rod with a hemispherical tip of 10 mm diameter which was advanced along the inguinal canal from within the pelvis. The rod was advanced from deep to superficial at a constant rate of 0·5 mm/s and the maximum force measured on a 1-kN load cell The direction of the inguinal canal was previously determined radiographically Both the repaired and the normal non-herniated sides were tested. The specimens were then examined macroscopically to determine where disruption had occurred.

Results

The group characteristics are shown in *Table 1*. The time taken to perform a laparoscopic inguinal hernia repair in the pig was significantly less than that for open repair ($P<0·05$; *Table 1*). There was no significant difference in preoperative or final weights, defect size, mesh size or recovery time between the groups.

There were no clinical recurrences during the 4 weeks following surgery in either group and no disrupted repairs were seen before stress testing. Stress testing was performed in all 11 animals. *Fig. 3* shows a typical graph, obtained during testing, where the applied force increased as the metal rod travelled down the inguinal canal in both an open and a laparoscopic repair. The slope of the graph becomes steeper as the elastic limit of the tissue is reached. The sudden drop that follows represents the complete disruption of the repair. Irreversible deformation occurs if the elastic limit is exceeded ('yield point') and a further load increase leads to rupture of the tissue ('break point').

Table 1 Group characteristics

	Laparoscopic ($n=6$)	Open ($n=5$)
Operating time (min)	42·5 (30–55)*	60·0 (45–75)
Defect size (cm^2)	3·3 (2–4)	2·6 (1–4)
Mesh size (cm^2)	19·3 (17–24)	13·5 (8–20)
Preoperative weight (kg)	13·6 (10–20)	12·0 (9–20)
Final weight (kg)	30·3 (24–50)	27·0 (24–30)
Recovery time (min)	47 (30–60)	53·0 (45–60)

Values are mean (range) $^*P<0·05$ *versus* open repair (Student's *t* test)

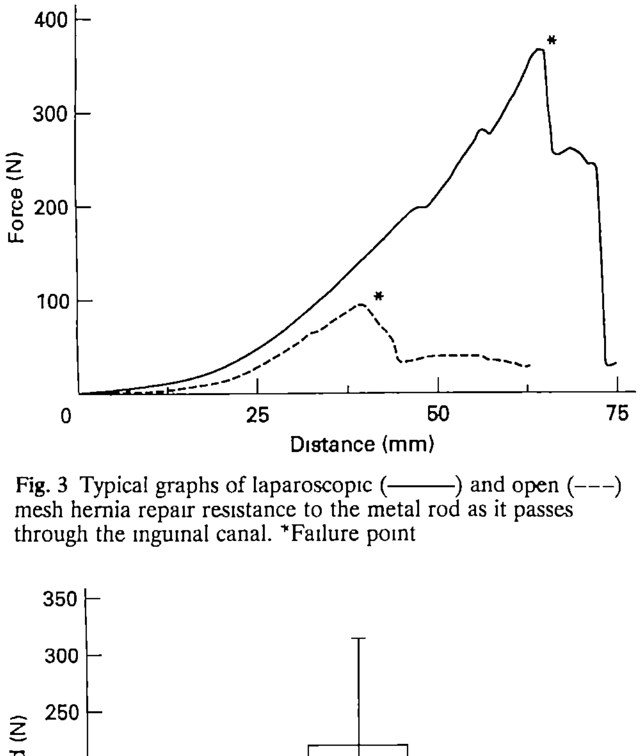

Fig. 3 Typical graphs of laparoscopic (———) and open (- - -) mesh hernia repair resistance to the metal rod as it passes through the inguinal canal. *Failure point

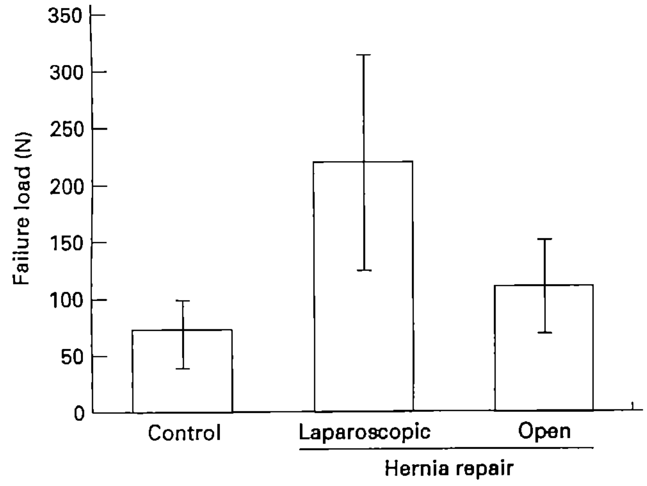

Fig. 4 Mean load required to disrupt the normal inguinal canal, and laparoscopic and open mesh repairs. Error bars represent one standard deviation

The open repair was seen to fail at lower loads than the laparoscopic repair. In the latter there were some small steps in the loading curve, where small partial failures occurred, although these were not classified as the failure load or break load.

The open hernia repair (mean(s.d.) disruption force 110·3(41·4) N) was significantly stronger than the normal side (68·6(30·1) N); $P=0·02$) but the laparoscopic hernia repair (220·0(95·2) N) was significantly stronger than both the open repair ($P=0·04$) and the normal inguinal canal ($P=0·01$; *Fig. 4*).

After testing, the specimens were excised and examined macroscopically to determine the nature of the stress-induced disruption points. Three of the five open repairs showed disruption as a result of upward displacement of the mesh and the abdominal wall *en bloc*. This was caused by avulsion of the anterior abdominal wall and inguinal ligament from their insertion on the pelvis. This eventually allowed the probe to travel down the deformed femoral canal. The fourth failed because the inferomedial corner of the mesh became detached over the pubic tubercle and the fifth because the anterior abdominal wall ruptured around the superior border of the mesh.

The cause of disruption in four of the six laparoscopic repairs was detachment of the mesh at the inferomedial border. The fifth mesh gave way at the superior margin and in the sixth the mesh was completely detached and pushed down the inguinal canal.

Examination showed that the mesh remained intact throughout testing in both the laparoscopic and open groups.

Discussion

Testing the repairs to destruction required an animal model. The pig was chosen because some breeds have a high prevalence of congenital indirect inguinal hernia[21]. Inguinal hernia occurs in up to 5 per cent of the Large White/Landrace breed used in this study. The pig has been used in other studies of hernia repair[22-24] and is suitable because (1) the anatomy of the inguinal region is similar to that of the human, (2) it is large enough to allow laparoscopic procedures to be performed and (3) it can tolerate general anaesthesia and recovery well. Scrotal hernias in pigs are usually treated by castration[25] and although the laparoscopic repair has been described[22] this paper is the first report of open hernia repair in a pig. The open repair was difficult particularly when dissecting the delicate hernial sac from the cord and hence the open procedure took longer to perform than the laparoscopic repair.

The present study provides an objective method of measuring the force required to disrupt a hernia repair. In designing this study an attempt was made to recreate the pressure to which a repair would be subjected. Feasibility studies were performed which sustained intra-abdominal pressure at 138 Pa for periods of 5 min. However, no damage to the hernia repairs was seen. Applying pressure directly to the mesh was considered to be the best method of loading the repair. Testing to destruction exposes weak points that would be difficult to predict in a clinical study.

The laparoscopic inguinal hernia repair was found to be significantly stronger than the open repair and the normal side in the porcine model. The open repair was also stronger than the normal inguinal canal. The strength of both repairs in comparison to the normal side confirms the efficacy of polypropylene mesh for strengthening the inguinal canal during hernia repair. The difference in strengths between laparoscopic and open repair may be explained by the position of the mesh in relation to the defect. Once an open repair started to fail, where the mesh was superficial to the defect, then failure proceeded rapidly. In the laparoscopic repair the internal placement allowed greater overall strength even if some early failure had occurred.

When the laparoscopic repair disrupted under testing, this usually occurred as a result of detachment of the mesh. Four of the six meshes detached at the inferomedial border; this is an area where adequate overlap is vital. This weak point has been noted in recent papers looking at recurrence following laparoscopic repair[26,27]. One detached from the superior border and again sufficient overlap of the defect is mandatory here. The potentially correctable weak point in the open mesh repair is where the inferomedial border of the mesh overlies the pubic tubercle. This area failed under testing in one of the experimental repairs. This has been noted by others[19] in the clinical situation.

Previous biomechanical studies have attempted to devise objective criteria to compare hernia repairs. Stress testing of the transversalis fascia has suggested an inherent weakness in the fascia which predisposes to herniation with loading curves similar to those produced in the present study[28]. Further studies have suggested a defect in collagen synthesis[12,29,30]. Previous assessments of suture tension in the Bassini repair and the aponeurotic repair have suggested that a tension-free repair could withstand the stress induced by intra-abdominal pressure[11]. The bursting strengths of mesh and sutured repairs of the abdominal wall[31,32] and breaking points of different mesh–staple combinations[33] have been evaluated previously. This study is the first to design a model to test the strength of hernia repairs *in situ*.

Whether the greater strength of the laparoscopic hernia repair will translate into better long-term results and a lower recurrence rate remains to be seen. It would seem likely that the strongest repair at 4 weeks after an operation should have an advantage. Further studies looking at other time periods and methods of repair are required. This model for testing hernia repairs may highlight unsuspected weak points and allow modifications for clinical use.

Surgical workshop

A new way to prevent leakage of glycine during endoscopic transanal resection of rectal lesions

F. ABBASAKOOR and R. B. STEPHENS

Department of Surgery, St James's Hospital, James's Street, Dublin 8, Ireland

Correspondence to: Mr R. B Stephens

Since endoscopic transanal resection was first described by Lindenschmidt *et al.*[1] in 1977, it has earned a limited but valuable place in colorectal surgery. Satisfactory long-term outcome may be achieved for patients with benign rectal lesions and acceptable results have been obtained for those in whom conventional surgery would carry unacceptable risks, notably the elderly with advanced cancer or those with severe concurrent illness[2].

Leakage of glycine during the procedure can be a problem. This paper describes the use of a modified endotracheal tube in conjunction with existing urological resectoscopes to overcome this problem.

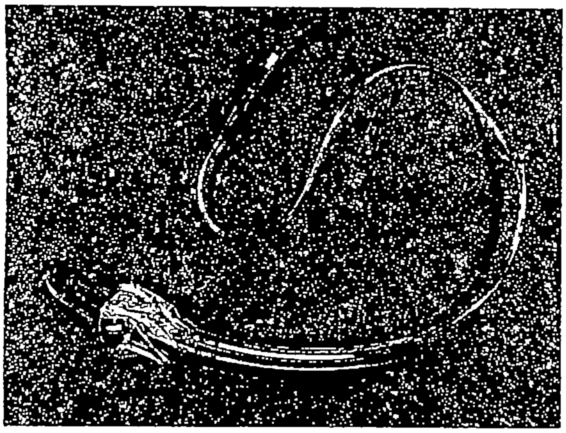

Fig. 1 The modified endotracheal tube with preservation of the insufflator channel

Surgical technique

The patient undergoes full bowel preparation before operation to minimize the potential risk of perforation. Antibiotic prophylaxis is administered intravenously at the time of induction of anaesthesia. The operation is performed under general or spinal anaesthesia with the patient in the lithotomy position.

A standard 24-Fr urological resectoscope (Circon, American Cystoscope Manufacturing Incorporated, Stanford, Connecticut, USA) with its 30° telescope is inserted through an endotracheal tube that has been modified by halving its length, while preserving the channel to insufflate the cuff (*Fig. 1*). This is simply carried out with a pair of heavy scissors. A size 10 endotracheal tube (Mallinckrodt ID 10; Mallinckrodt Medical, Athlone, Ireland) fits the resectoscope perfectly. The cuff prevents leakage of glycine and its size can be altered to fit the anal opening, usually with 15–20 ml of air.

Discussion

Endoscopic transanal resection needs to be performed under low pressures of 20–30 cm glycine to minimize the risks of perforation, and some peranal leakage is therefore a useful safety valve. However, major leakage and insufficient rectal distension is a particular problem when using the 24- or 27-Fr urological resectoscopes. Reliance on anal sphincter tone alone has been found to be adequate by some[3], but in the present authors' experience it is not always reliable for achieving good rectal filling at low pressures. The use of a specially adapted Lord's dilator has been described[4] to prevent leakage. Endoscopic transanal resection of rectal lesions is increasing in popularity. The ability to perform this operation in any hospital with existing urological instruments and a modified endotracheal tube as a simple, cheap and effective way of preventing leakage is appealing.

Correspondence to. Dr T. Cundy

The surgical treatment of obesity can have adverse effects on bone, but there are few published data on the effects of vertical-banded gastroplasty. Serial measurements of bone mineral density at the lumbar spine and three upper femoral sites, using dual-energy X-ray absorptiometry, and also of biochemical indices of bone and mineral metabolism at intervals up to 2 years after operation were performed in 18 patients with morbid obesity who had vertical-banded gastroplasty. Bone mineral density measurements were also made in age- and sex-matched non-obese controls. Bone density before operation was significantly greater in the obese than in the controls ($P<0\cdot02$ at all sites). The obese patients lost weight rapidly after vertical-banded gastroplasty (mean weight loss 29 kg at 1 year, $P<0\cdot001$). This was accompanied by a measurable loss of bone density from the trochanter and Ward's triangle sites in the upper femur ($P<0\cdot05$), but not from the lumbar spine. Bone density values remained stable over 14 months in the controls. Hydroxyproline excretion increased significantly ($P<0\cdot005$), indicating an increase in bone resorption. Alkaline phosphatase levels decreased significantly ($P<0\cdot001$), but this probably represents the reversal of hepatic steatosis. There was no evidence of hyperparathyroidism or vitamin D deficiency. In conclusion, vertical-banded gastroplasty causes modest bone density loss from femoral sites, but not the lumbar spine. The difficulties of assessing bone density changes in the obese are discussed.

Body-weight is an important determinant of bone mineral density, and overweight people have been shown consistently to have higher bone density than the non-obese[1–4]. There is, however, considerable uncertainty about whether weight loss in the obese is accompanied by loss of bone density. Some studies have reported that there is little or no effect of weight loss on bone density[5,6], whereas others have found variable degrees of bone loss[7–11]. In some of these studies the reported rate of bone loss has been remarkably rapid[10,11].

Vertical-banded gastroplasty is one of the most effective and rapid ways to help the obese to lose weight, but to the authors' knowledge only one of the published studies of the effect of weight loss on bone density has included any patients having this procedure[7]. Osteoporosis and secondary hyperparathyroidism are common sequelae of partial gastrectomy for ulcer disease[12,13] and may also occur after gastric bypass procedures for morbid obesity[14]. It is therefore possible that vertical-banded gastroplasty could result in significant bone loss and hyperparathyroidism with important long-term consequences. In this study bone density and biochemical indices of mineral metabolism were prospectively measured in a group of morbidly obese patients undergoing vertical-banded gastroplasty.

Patients and methods

Patients and surgical technique

Eighteen patients were studied before and after gastric restriction surgery for morbid obesity. Fourteen patients were premenopausal, two postmenopausal and two were men. Mean age was 37 (range 23–54) years The operation performed in each patient was vertical-banded gastroplasty in which a gastric pouch of 20 ml was created[15]. Patients were counselled extensively before the procedure and adhered to a weight-reducing diet for several weeks before the operation.

Bone density measurements were made at the time of operation and at 6, 12 and 24 months after surgery. At these times patients were weighed wearing light indoor clothing using electronic scales, and blood and urine samples were collected for biochemical analyses. All patients continued regular supervision from a dietitian in the postoperative period and were also prescribed a daily supplement of one multivitamin tablet (containing 7·5 μg calciferol). Calcium supplements were not prescribed.

Bone density measurements in the obese patients were compared with those from 18 control subjects matched individually for age and sex, but not for body-weight (*Table 1*). Two bone density measurements from the controls, a mean of 14 months apart, were made.

Bone density measurements

Bone mineral density was measured in the lumbar spine (posteroanterior projection) and at three sites in the upper femur (femoral neck, trochanter and Ward's triangle) using dual-energy X-ray absorptiometry (Lunar DPX-L, software version 1·2, Lunar Corporation, Madison, Wisconsin, USA). The precision of these measurements in the authors' laboratory is 1·0 per cent for the lumbar spine, 1·4 per cent for the femoral neck, 2 9 per cent for Ward's triangle and 1·6 per cent for the trochanter.

Biochemical measurements

The biochemical assessments (obese patients only) included total plasma calcium (adjusted for plasma albumin) and plasma concentrations of phosphate, magnesium, 25-hydroxy vitamin D, 1,25-dihydroxy vitamin D, parathyroid hormone and (in women only) free testosterone[16]. The plasma activities of the enzymes aspartate aminotransferase (AST), γ-glutaryl transpeptidase (γGT) and alkaline phosphatase were also measured. Hydroxyproline excretion was assessed in a fasting urine sample and expressed as the hydroxyproline : creatinine molar ratio.

Statistical analysis

Student's *t* test for paired samples was employed for within-group comparisons. Differences between patients who had gastroplasty and controls were also assessed by the paired *t* test

Paper accepted 12 December 1995

on the matched pairs of patients. Correlations were calculated by Pearson's method. Results are given as mean and 95 per cent confidence interval (c.i.) unless otherwise stated. The study was approved by the local research ethics committee.

Results

Gastric restriction surgery was successful in reducing weight in most patients. Mean weight loss was 24 (range 1–39) (95 per cent c.i. 20–29) kg at 6 months, 29 (range 3–70) (95 per cent c.i. 22–36) kg 1 year and 24 (range 7–39) (95 per cent c.i. 18–30) kg at 2 years (all values $P < 0·001$ *versus* preoperative weight), representing a mean weight loss of 21·3 per cent at 6 months, 24·9 per cent at 1 year and 21·4 per cent at 2 years. Expressed as the percentage excess over ideal body-weight, this fell

AST, aspartate aminotransferase; γ-GT, γ-glutaryl transpeptidase *$P<0{\cdot}05$, †$P<0{\cdot}02$, ††$P<0{\cdot}01$, ‡$P<0{\cdot}005$, §$P<0\ 002$, **$P<0{\cdot}001$ *versus* initial values (paired t test)

from a mean of 108 per cent before operation to 64 per cent at 6 months, 56 per cent at 1 year and 63 per cent at 2 years. Mean body-weight remained stable in the controls.

At baseline, bone density was significantly greater in the obese patients than in the controls at all sites (*Table 1*), and it remained stable at all four sites in the control subjects. Patients undergoing gastroplasty showed some loss of bone density from the femoral sites, particularly from Ward's triangle (mean loss 3·9 (95 per cent c.i. 0·3–7·5) per cent at 2 years, $P<0{\cdot}05$) and the trochanter (mean loss 4·0 (c.i. 0·5–7·5) per cent at 1 year and 4·8 (c.i. 0·2–9·4) per cent at 2 years, both $P<0{\cdot}05$, *Fig. 1*). The loss of bone from the trochanter was significantly greater in the eight patients who lost the most weight by 6 months (25 per cent or more of presurgery body-weight) than in the ten who lost 21 per cent or less ($P<0{\cdot}02$ at 1 year, $P<0{\cdot}005$ at 2 years, Students t test) but there were no direct correlations between the changes in bone density and body-weight.

Mean values for lumbar spine bone mineral density as a whole did not change over the 2-year follow-up in the patients who had gastroplasty. Only three patients had decreases of more than 5 per cent in lumbar spine bone density. These were the two men and one premenopausal woman aged 36 years at the time of surgery; the woman became amenorrhoeic shortly after her operation and measurements of plasma follicle-stimulating hormone confirmed that she had developed premature menopause. She took hormone replacement therapy in the second year of the study.

Sequential measurements of biochemical parameters in the obese patients undergoing gastroplasty showed significant reductions in plasma calcium at the 2-year point only, and in free testosterone. Plasma alkaline phosphatase activity also decreased significantly, as did the activity of the liver-derived enzymes γGT and AST. The fasting urine hydroxyproline : creatinine ratio increased transiently, but returned to baseline levels by 2 years. There was also a small increment in mean plasma 25-hydroxy vitamin D. Plasma concentrations of magnesium, phosphate and 1,25-dihydroxy vitamin D did not change (*Table 2*).

Discussion

This study has confirmed that bone mineral density is increased in the obese and that vertical-banded gastroplasty is highly effective at inducing weight loss in most patients. Although the mean weight loss was impressive, the changes in bone density were modest, with significant losses from the trochanter and Ward's triangle sites at the hip, but no loss from the lumbar spine. Despite the small number of patients the authors are able to demonstrate some relationship between bone loss and weight loss, as the patients who lost most weight had the greatest decline in bone density at the trochanter.

The literature examining the effects of weight loss on bone is difficult to summarize, in part because the degree of weight loss attained has differed between studies but also because the sites at which bone has been measured, the duration of the studies, the type of densitometers and their software, and the way of expressing the results (bone mineral content or bone mineral density) have also varied. Even considering these variables some of the findings are difficult to reconcile. For example, in the prospective study of Krolner *et al.*[7], there was a mean loss of 28 per cent body-weight and 7·2 per cent bone mineral content of the lumbar spine, as measured by dual photon absorptiometry in 14 patients who had either gastric bypass or vertical-banded gastroplasty. In the study by Jensen *et al.*[11], in which 52 patients consumed a very low calorie diet, mean weight loss was 12·5 per cent over 15 weeks and was accompanied by a decrease of 6·9 per cent in the bone mineral content of the trunk, as measured by dual-energy X-ray absorptiometry. These results contrast markedly with the findings in the present study of unchanged spinal bone density over 2 years, despite massive weight loss. Studies of forearm bone density changes have also yielded disparate results[5,9].

Such discrepancies suggest that considerable methodological problems arise when measuring bone density (or mass) in the obese. These have been demonstrated in several studies using absorptiometry techniques[5,17–20]. The thickness of soft tissue around a bone reduces the proportion of X-rays (or photons) surviving attenuation, and interferes with bone edge detection. The effect of fat may vary according to the quantity present and its distribution within the abdomen, and also varies between different makes of densitometer[19], and with different versions of software. Increased thickness of soft tissue can also change the apparent area of bone measured, which presumably explains the surprising differences between changes in bone mineral content and bone mineral density noted in some studies[10]. In general, when bone density results are reported, the bone 'loss' associated with weight loss is much less marked[6]. Manufacturers of the software for commercial densitometers have recognized these artefacts and attempted to correct them in recent versions such as the one used in this study (R. Mazess, Lunar Corporation, personal communication). However, it remains possible that some artefacts persist. Experiments in which lard is layered on to the abdomen, or a phantom, to simulate the effects of obesity[8,11,20] may not always be effective in defining such artefacts, because the effects of fat on bone mineral measurements depend on its regional distribution[19].

The loss of bone observed appears to have resulted from an increase in bone resorption, as indicated by the increased excretion of hydroxyproline, an effect also noted in other studies[6,9,10]. Weight loss in the obese may also be accompanied by increases in markers of bone formation[6,9], indicating that bone turnover is increased during weight loss. In the present study alkaline phosphatase activity decreased significantly, but this cannot be interpreted as a reduction in bone formation, as γGT and AST also declined, suggesting that the reduction in alkaline phosphatase was probably the result of a reversal of hepatic steatosis. Although a decrease in plasma calcium was noted at the 2-year point, neither parathyroid hormone nor 1,25-dihydroxy vitamin D were increased at any stage in the study. These results provide assurance that the bone sequelae of partial gastrectomy, gastric bypass and intestinal bypass procedures are unlikely to complicate vertical-banded gastroplasty. However, it should be noted that these problems characteristically present several years after surgery[12–14,21], so that follow-up for longer than 2 years would be necessary to ensure that late bone disease did not occur.

In the absence of hyperparathyroidism, the stimulus to increase bone resorption is not clear. The reduction in free testosterone in the female patients (presumably a result of decreased peripheral androgen production) may have some relevance, but the distinct pattern of loss that was observed (femur greater than lumbar spine) suggests that the bone loss was related to decreased weight bearing rather than changes in sex steroids. There is evidence from cross-sectional studies (in older men and women) that the relationships between body-weight and bone density are strongest at weight-bearing sites[22]. Most patients in the present study were premenopausal women and it is possible that the effects of the procedure may differ in postmenopausal women.

In previous studies, the authors[23,24] have highlighted the strong relationships between bone density and total body fat in both premenopausal and postmenopausal women. The relatively small reduction in bone density noted in this study, despite the large loss of weight, suggests that the relationship between fat and bone density may not be linear over the wide range from normal to the morbidly obese. It should be remembered that this procedure did not turn obese patients into normal weight individuals. One year after operation the patients remained significantly heavier than the control subjects (mean weight 89 *versus* 64 kg, $P < 0{\cdot}001$), and some 56 per cent above ideal body-weight.

It is concluded that vertical-banded gastroplasty for weight reduction in the obese is accompanied by loss of bone from the hip sites but not the spine. The bone loss appears to result from a transient increase in bone resorption. There is no evidence that vertical-banded gastroplasty induces secondary hyperparathyroidism, vitamin D deficiency or hypomagnesaemia.

Selective approach to the treatment of oesophageal cancer

T. JUNGINGER and P. DUTKOWSKI

Department of General and Abdominal Surgery, University of Mainz, Germany
Correspondence to: Professor T Junginger, Klinik f Allgemein-und Abdominalchirurgie, Universitat Mainz, Langenbeckstrasse 1, 55 101 Mainz, Germany

Between September 1985 and December 1994, 322 patients with oesophageal cancer were treated. Of the 190 patients who underwent operation, 173 had an oesophageal resection; in 124 this was performed as an abdominothoracic resection and in 49 by the transhiatal approach. The assessment of radicality after histological examination revealed a curative (R_0) resection in 121 patients (70 per cent) and a palliative (R_1–R_2) resection in 52 (30 per cent). Prognosis was correlated with the extent of mediastinal lymph node dissection. In 77 patients with stage pT_{1-3} pN_{0-1} pM_0 the 5-year survival rate was 40 per cent after abdominothoracic resection with two-field lymph node dissection and zero after transhiatal resection ($P = 0{\cdot}01$). The authors propose a differentiated surgical approach involving abdominothoracic resection with two-field lymph node dissection for patients with limited tumours (pT_{1-3} pN_{0-1} M_0) if the operative risk is tolerable. Transhiatal resection appears to be effective only in patients with early tumours (Union Internacional Contra la Cancrum stage 0).

There is controversy about the prognostic influence of the surgical procedure in patients with oesophageal cancer. Bolton *et al.*[1] and Goldminc *et al.*[2] reported no prognostic difference between transthoracic and transhiatal approaches. However, there is evidence for improvement in survival for certain tumour stages following three-field lymph node dissection[3]. In addition, a European multicentre study in patients with submucosal oesophageal cancer[4] showed a better prognosis after transthoracic than following transhiatal resection.

In the authors' institution the abdominothoracic approach is used routinely, but patients with a higher operative risk because of pulmonary complications undergo transhiatal resection. The aim of this prospective non-randomized observational study was to determine whether extended lymphadenectomy in transthoracic resection produces an improvement in outcome. An important question is whether the different indications for the two operative procedures limit the comparability of the groups. Special attention was therefore paid to structural similarity by univariate and multivariate analysis. Independent prognostic factors were identified by regression analysis.

Patients and methods

Between September 1985 and December 1994, 322 patients with histologically proven squamous carcinoma or adenocarcinoma of the oesophagus were treated. Some 109 patients already had multiple distant metastasis at admission and underwent palliative non-surgical treatment. Twenty-three patients with an irresectable tumour had a palliative bypass procedure (endotubus). Of the 190 patients who underwent operation, 17 had an exploratory laparotomy which showed a more advanced tumour than expected. In two cases an endotubus was placed at this time.

Prognostic factors were analysed in the remaining 173 patients, who underwent primary resection. This was performed in 124 cases by the transthoracic approach and in 49 by the transhiatal approach (*Fig. 1*).

Transthoracic resection was carried out using the abdominal and right thoracic route with *en bloc* oesophagectomy and proximal gastrectomy, as described by Akiyama[5]. In addition to the mediastinal lymph nodes (upper, middle and lower thoracic paraoesophageal lymph nodes, paratracheal lymph nodes, para-aortic thoracic lymph nodes, right and left recurrent nerve lymph nodes, pulmonary hilar and diaphragmatic lymph nodes), the parietal pleura and thoracic duct were resected. The branches of the azygos vein, the pericardium and the opposite pleura were not resected if there was no tumour infiltration (biopsy was performed routinely). Transhiatal resection included resection of the paraoesophageal lymph nodes that could be reached. Abdominal lymph node dissection was performed similarly in both operative procedures with complete dissection of the coeliac lymph nodes between the right gastric artery and splenic hilum. Gastrointestinal continuity was restored by gastric pull-through in 162 patients (94 per cent) or colonic interposition in 11 (6 per cent). After transthoracic resection a high intrathoracic anastomosis was performed in 99 patients (57 per cent) between the oesophagus and the back wall of the stomach using a circular surgical stapler. The cervical anastomosis in 74 patients (43 per cent) was hand sewn.

The median age of the resected patients was 56 (range 29–84) years; 146 (84 per cent) were men. The tumour was located in the upper third of the oesophagus in 16 patients (9 per cent), in the middle third in 71 (41 per cent) and in the distal third in 84 (49 per cent). The pathological tumour node metastasis (pTNM) and R category were assessed according to the Union Internacional Contra la Cancrum (UICC) 1992 classification[6] by an experienced pathologist. Tumour type and differentiation were classified according to World Health Organization criteria[7]. The presence of lymphatic invasion was documented and the removed mediastinal and abdominal lymph nodes were counted carefully. The resection margins (proximal, distal and mediastinal) were marked to estimate clearance.

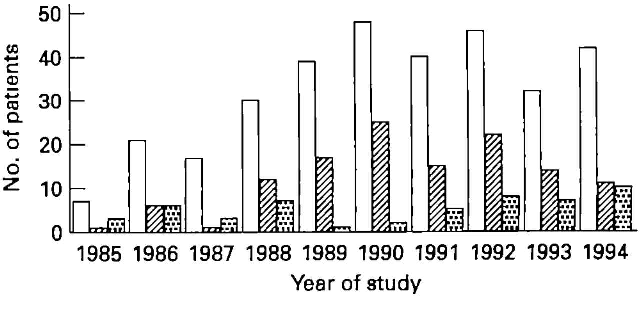

Fig. 1 Distribution of 322 patients with oesophageal carcinoma (□) in the years 1985–1994, and treatment of 173 patients by transthoracic (▨) ($n = 124$) or transhiatal (□) ($n = 49$) resection

---

Paper accepted 14 January 1996

The assessment of radicality after histological investigation revealed a curative (R_0) resection in 121 patients (70 per cent) and a palliative (R_1–R_2) resection in 52 (30 per cent).

A prospective protocol was used to record the surgical and general complication rates as well as the duration of intensive care, 30-day mortality, hospital mortality and survival. The deadline for data collection was December 1994. Follow-up was complete for all 173 patients, with a median of 28 (0–99) months in the 49 survivors (28 per cent).

Univariate and multivariate analysis were performed with the χ^2 test, Fisher's exact test, the Mann–Whitney *U* test, the Kruskal–Wallis test, Cox's proportional hazard model and logistic regression. Survival rates were calculated according to Kaplan and Meier, and are given as observed overall survival including postoperative deaths. Significant differences in survival were determined with the log rank test.

All statistical analyses were performed on a personal computer using Superior Performing Software Systems (SPSS for Windows, version 6.0.1; SPSS, Munich, Germany).

Results

Histological examination revealed squamous cell carcinoma in 106 patients (61 per cent) and adenocarcinoma of the oesophagus in 45 (26 per cent); 22 (13 per cent) of the resected patients had an anaplastic tumour. Forty-eight patients (28 per cent) had a tumour classed as stage pT_{1-2}, whereas 125 (72 per cent) had an advanced tumour of stage pT_{3-4}. In 118 patients (68 per cent) regional lymph nodes were involved (pN_1) and in 48 (28 per cent) the coeliac nodes were involved ($pM_{1\,lym}$) (*Tables 1–3*).

Morbidity

Complications occurred in 81 patients (47 per cent). The general complications were adult respiratory distress syndrome in 13 patients (8 per cent), severe pneumonia in 17 (10 per cent), psychosis in nine (5 per cent), heart failure in six (3 per cent), pulmonary embolism in three (2 per cent) and myocardial infarction in two (one per cent). The surgical complications were paralysis of both recurrent nerves in 15 patients (9 per cent), anastomotic

ASA classification				
I–II *versus* III–IV	−0·39	0·19	0·67	0·04

The seven independent variables analysed were patient age, tumour length, operative method, pathological tumour (pT) category, American Society of Anesthesiologists (ASA) classification, tumour localization and number of removed mediastinal lymph nodes

leakage in 13 (8 per cent), wound infection in eight (5 per cent), chylothorax or serothorax in seven (4 per cent), perioperative bleeding in three (2 per cent), interposition necrosis in one (1 per cent) and tracheo-oesophageal fistula in one (1 per cent).

The overall morbidity rate after transthoracic resection was not significantly different from that following transhiatal resection (51 *versus* 37 per cent respectively). The logistic regression analysis included seven variables and identified as independent factors for morbidity the pT category, patient age, American Society of Anesthesiologists (ASA) classification and tumour localization (*Table 4*).

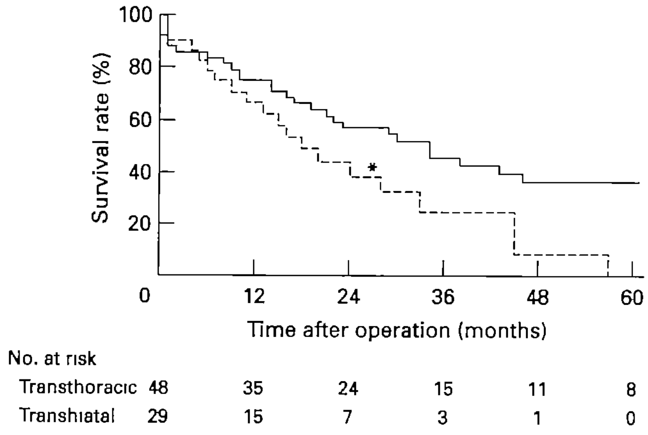

Fig. 1 Distribution of 322 patients with oesophageal carcinoma (□) in the years 1985–1994, and treatment of 173 patients by transthoracic (▨) ($n=124$) or transhiatal (□) ($n=49$) resection

Mortality

The 30-day mortality rate was low after both operative procedures. Ten patients (8 per cent) died after transthoracic resection and three (6 per cent) after transhiatal resection.

Hospital mortality rate after the transthoracic approach was 15 per cent (18 patients) but there was no significant difference compared with transhiatal resection ($P=0·26$). In univariate analysis the tumour length and pT category showed a significant effect on hospital mortality ($P=0·005$ and $P=0·04$ respectively). In addition there was a tendency towards higher mortality in patients with nodal invasion (pN_1), in those classified higher than ASA II and with increasing extent of mediastinal lymph node dissection. Regression analysis was not possible because of the small number of events (22 in 173 patients).

Prognosis

The actuarial 5-year survival rate of all 173 resected patients was 16 per cent, including postoperative hospital mortality. The 5-year survival rates were higher for all UICC stages after the transthoracic procedure. In 77 patients with tumour stage $pT_{1-3}\,pN_{0-1}\,pM_0$, median survival after transthoracic resection was significantly higher than that after transhiatal resection (34(8·3) *versus* 18(3·7) months, $P=0·03$) (*Fig. 2*).

Multivariate analysis of ten variables (Cox proportional hazard model) identified pT category, pM category, lymphatic invasion, operative method and curative resection as independent prognostic factors (*Table 5*).

Lymph node dissection

The number of examined abdominal lymph nodes was similar after both operative procedures ($P=0·15$), whereas the number of examined mediastinal lymph nodes was much higher after transthoracic resection with a two-field lymph node dissection. To clarify the importance of mediastinal lymph node dissection total survival was investigated separately in 77 patients without distant metastasis or tumour infiltration of adjacent structures ($pT_{1-3}\,pN_{0-1}\,pM_0$).

In this subgroup, transhiatal resection (group 1, $n=29$)

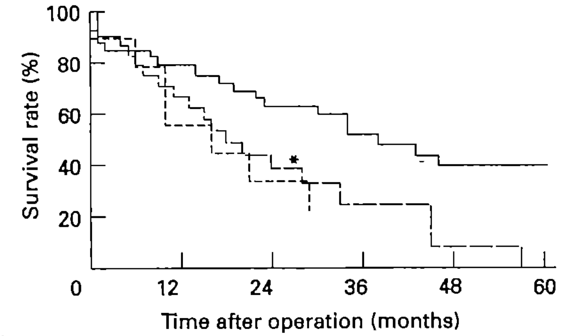
Transthoracic *versus* transhiatal	−0·29	0·12	1·34	0·02

The ten independent variables analysed were operative method, lymphatic invasion, curativity, pathological tumour node metastasis (pTNM) categories, American Society of Anesthesiologists classification, patient age, tumour localization and tumour histology



No. at risk	0	12	24	36	48	60
Groups 3 and 4	39	30	21	13	9	8
Group 2	9	5	3	2	2	0
Group 1	29	15	7	3	1	0

Fig. 2 Survival after transthoracic (———) and transhiatal (– – –) resection in 77 patients with limited tumour stage (pT_{1-3} pN_{0-1} M_0). *$P = 0·03$ (log rank test)

was compared with transthoracic resection according to the number of examined mediastinal lymph nodes: group 2, 0–5 (median 2) nodes ($n = 9$); group 3, 6–15 (median 10) nodes ($n = 18$); group 4, 16–67 (median 28) nodes ($n = 21$).

Survival time was similar in groups 1 and 2. On the other hand, the median total survival increased with increasing number of resected mediastinal lymph nodes (group 1, 18(3·7) months; group 2, 16(8·9) months; group 3, 43(10·1) months; group 4, 34(10·1) months). Between groups 3 and 4 there was no additional significant prognostic difference. Patients in groups 3 and 4 together had prolonged survival compared with those having transhiatal resection (median(s.e.m.) 38(7·3) months, $P = 0·01$) (*Fig. 3*).

No significant differences were shown (group 1 *versus* groups 3 and 4) in patient age, length of intensive care, tumour length, ASA classification, sex distribution, tumour localization, tumour grading, pT category, pN category, morbidity and mortality (data not shown).

The 5-year survival rate of patients in groups 3 and 4 was 40 per cent whereas none of those in group 1 is alive 5 years after surgery (*Fig. 3*).

Discussion

Reduction of the operative risk and improvement in prognosis are the goals of every operation and are the decisive criteria in selection of the surgical approach. There is still controversy about the value of local radicality in patients with oesophageal cancer, and especially regarding the importance of mediastinal lymph node dissection. Several authors[1,2,8,9] have recommended the transhiatal procedure because of the reduction in operative risk. Others[3,10–12] have extended lymph node dissection up to the cervical field and report a better prognosis. Bonavina[4] also showed a higher 5-year survival rate in patients with submucosal oesophageal cancer after transthoracic resection compared with transhiatal oesophagectomy; however, he did not describe the quality of the lymph node dissection. Horstmann *et al.*[13] reported similar low survival rates for both operative procedures (21 and 17 per cent after 3 years), but they did not state the number of mediastinal and abdominal lymph nodes examined.

In the present authors' institution the procedure of choice for patients with oesophageal cancer is abdominothoracic *en bloc* resection, mediastinal lymph node dissection and restoration of gastrointestinal continuity by gastric pull-through. In high-risk patients, however, the transhiatal approach is preferred if this is practicable. During the period under consideration, one-quarter of the patients had transhiatal resection and three-quarters had a transthoracic approach with progressive extension of the mediastinal lymph node dissection with time. The aim of the prospective follow-up was to identify situations in which mediastinal lymph node dissection is useful and necessary, and those in which it is without benefit. Because a randomized study is not possible on ethical grounds, this study was performed by comparing prospectively collected data.

Because of the different indications for operation, morbidity and mortality are not comparable between the two approaches. The transhiatal resection was performed in patients with limited functional reserve and with limited tumour size. Seventy-eight per cent of these patients were in the ASA group III–IV (compared with 65 per cent of those who had transthoracic resection). However, the postoperative morbidity and mortality rates, as well as the duration of intensive care, were lower following transhiatal resection. On the other hand, patients in the transthoracic group had large tumours which more frequently could not be resected for cure. This explains the higher morbidity and mortality rates after this approach. In regression analysis only tumour and patient factors (pT_4 category, proximal and middle third tumour location, age over 60 years and ASA grade over II) were identified as independent factors for morbidity.

The prognostic factors tested were, first, tumour-related factors such as pT category, invasion of coeliac lymph nodes (pM_l) and lymphatic invasion, and, second, surgical factors like curativity and choice of operative method. In this analysis the surgical factors were of particular importance in 103 patients (60 per cent) with limited tumour stage (pT_{1-3} pN_{0-1} pM_0). The curatively resected patients of this group ($n = 77$) were therefore analysed with special emphasis on mediastinal lymph node dissection (groups 1–4).

Comparison of the prognosis of two operative methods with different radicality is always difficult because of staging factors; the N_0 patient group may incorrectly include some patients with metastases in the transhiatal group. Nevertheless, in ten of 15 patients in group 1 classified as pN_0 after transhiatal resection, the number of examined tumour-free lymph nodes (abdominal and mediastinal) was over ten. Seven of these patients were classified as stage N_0 by endosonography before resection and are still alive.

Despite this methodological difficulty, mediastinal lymph node dissection in transthoracic resection (groups 3 and 4) was associated with longer survival than transhiatal resection (group 1) or transthoracic resection without lymph node dissection (group 2).

These results suggest that survival benefit can be achieved in patients suffering from oesophageal cancer if the disease is limited (T_{1-3} N_{0-1} M_0) and curative *en bloc* resection including mediastinal lymph node dissection is performed. In the authors' opinion the reasons for this are a higher number of removed invaded lymph nodes or resection of micrometastases in apparently uninvolved lymph nodes.

Akiyama *et al.*[3] reported a clear benefit in patients with additional cervical lymph node dissection (three fields). Baba *et al.*[10] and Lerut and co-workers[11] have also emphasized the value of three-field lymph node dissection. However, their 5-year survival rate for patients with UICC stage I and II disease, and overall 5-year survival rate after curative transthoracic resection with two-field lymph node dissection, are similar to those reported here.

Survival was independent of mediastinal lymph node dissection in patients with an advanced oesophageal tumour (pT_4) or following resection of distant metastasis (liver, lung); palliative procedures are feasible in these situations. If the coeliac lymph nodes were invaded, survival decreased remarkably. There were few such cases and no distinction could be made between the two operative methods in this situation.

The results of this study suggest that selection of the operative approach may be based on the following criteria: (1) if preoperative staging by endosonography suggests UICC stage 0, the transhiatal approach might be regarded as appropriate; (2) in patients with advanced disease (pT_4, pM_1) the transhiatal approach is appropriate because of lower operative risk and unimprovable prognosis; and (3) in patients with limited tumour stage (pT_{1-3} pN_{0-1} pM_0) the abdominothoracic route with routine two- or three-field lymph node dissection should be chosen.

Mechanism for port-site metastasis after laparoscopic cancer surgery

Sir

We read with great interest the recent correspondence concerning the, as yet elusive, mechanism responsible for port-site tumour recurrence (*Br J Surg* 1986; 83. 133). Messrs Taffinder and Champault believe that airborne exfoliated tumour cells carried in the carbon dioxide leaking around the trocars, the so-called 'chimney effect'[1], may become trapped in the port wound surfaces, resulting in parietal recurrences. They should be congratulated on their success in isolating clumps of whole cells in the smoke aspirated during laparoscopic procedures; they have certainly made a good start. Still there is a long way to go: they have to prove the occurrence of three further events First, tumour cells have to be demonstrated in the smoke. Second, the tumour cells in aerosol form have to be shown to settle on the wound surfaces. Third, the implanted cells must be seen subsequently to grow into tumour nodules.

The authors revealed their plan to biopsy trocar sites to confirm tumour implantation In our hospital we have been examining biopsies diligently from all port sites following laparoscopic resection of colonic cancers and following resection of clinically evident port-site recurrences. To our surprise, in the case of a 61-year-old man with carcinoma of sigmoid colon, we found clumps of tumour cells with histological features of the primary growth in biopsies of both the camera and the right port wounds (*Fig 1*) We believe we are the first to provide hard evidence of tumour implantation.

Trocar site recurrence cannot be solely attributed to direct contact of the port wound with tumour-laden instruments. There have been reports of tumour recurrences occurring almost simultaneously in all ports, including the camera port which had not contacted either the cancerous specimen or the laparoscopic instruments[2–4]. Furthermore, in our studies on trocar biopsy, fragments of tumour tissue were seen buried deep in the abdominal wall muscle fibres. It looked as though they had been forcibly pressed into the muscle tissue (possibly propelled by the jet of carbon dioxide under pressure) However, the 'chimney effect' hypothesis cannot explain the development of malignant implants in chest wounds after thoracoscopic surgery in which carbon dioxide pneumoperitoneum was not used[5,6].

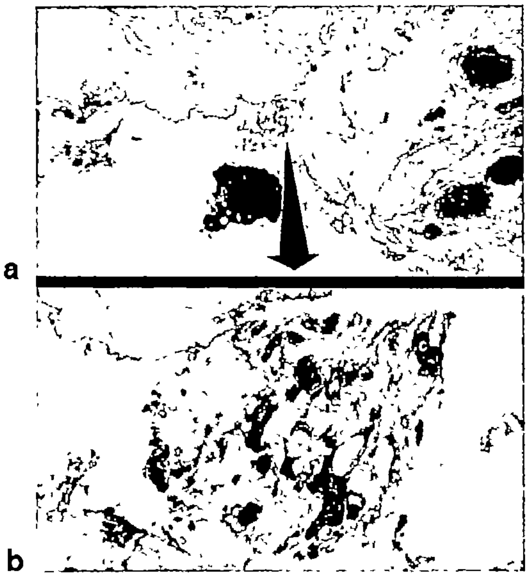

Fig. 1 a A clump of tumour cells is seen in the middle of tissues of the camera port biopsy (haematoxylin and eosin, original magnification ×40). b Magnified view of the clump of mucinous adenocarcinoma cells (haematoxylin and eosin, original magnification ×250)

Another possible mechanism is that, after deflation, the abdominal wall sags down, allowing the exfoliated tumour cells in the peritoneal fluid to be implanted into the undersurface of the port wound where the mesothelial cells are damaged or missing. While this mechanism might lead to parietal metastases extending from the peritoneal surface, it cannot account for recurrences localized only in the superficial subcutaneous fat (as in one of our five patients with proven recurrence)[7].

We believe, therefore, that multiple mechanisms are involved in the pathogenesis of port-site recurrence. Further basic scientific studies are necessary to unveil the whole mystery of this phenomenon.

Typhoid enteric perforation

Sir

I read with interest the study by Dr Akgun and colleagues (*Br J Surg* 1995; 82. 1512–15) on the management of typhoid enteric perforation and I congratulate them on collecting such a large series. Although I agree with many of their recommendations for the treatment of this difficult problem, I would like to point out that the conclusions they have drawn from their study are not supported by the data given. They have clearly demonstrated the direct relationship between mortality rate and the time interval from perforation to operation in their retrospective group (*Fig. 2* of article). We have demonstrated a similar relationship in a restrospective review over 5 years from July 1988 to June 1993 at our institution. We operated on 26 patients with typhoid enteric perforation: there were no deaths in patients with a perforation-to-operation interval of less than 48 h, one death in four patients with a history of 48–120 h, and four deaths in nine with a history of over 120 h. Perforation-to-operation interval is the single most important prognostic factor in patients wtih typhoid enteric perforation.

Although the authors state that the prospective group 'was not different from the retrospective series in any of the prognostic indices of age distribution, clinical signs and symptoms or laboratory findings', there is a clear difference between the two groups with respect to perforation-to-operation interval. They state that, in the retrospective group, only 65 (24 per cent) of 267 were admitted within 48 h of perforation and that this group had a mortality rate of 9·2 per cent. The vast majority of the retrospective group (76 per cent) was admitted after 48 h. In the prospective group 'the median interval between perforation and operation was 46 h', and there were four deaths in 34 patients. There were no patients with a history of over 5 days in the prospective group

From these data it is not justified to attribute the improvement in the outcome after typhoid enteric perforation to the changes made in their management. The overall improvement in mortality rate after operation could equally be explained by the earlier presentation of patients in the prospectively assessed group. To advocate 7 days of total parenteral nutrition (TPN) for a condition that primarily occurs in the world's poorest countries on the basis of this study may have the unfortunate consequence of diverting valuable resources away from more essential treatments to pay for TPN. I would certainly agree that aggressive preoperative fluid and electrolyte resuscitation is essential, and that antibiotics appropriate to local *Salmonella typhi* sensitivity and also covering anaerobic bacteria should be utilized. Our regimen involves vigorous fluid resuscitation using Ringer's lactate solution and antibiotic treatment with metronidazole and ciprofloxacin (80 per cent of local *S. typhi* strains are resistant to chloramphenicol)[1] In patients presenting less than 5 days after perforation (a group comparable to the prospective group in their study), we had only one death in 17 patients, which compares favourably with their results.

In summary, the study by Dr Akgun, although impressive in size, may be misleading because it fails to recognize the confounding effect of perforation-to-operation interval between the two groups. Similar results can be achieved in situations where TPN is not available provided the basic principles of adequate preoperative resuscitation and antibiotic treatment are practised

Author's reply

Sir
I am pleased that our article has been of interest, and I am glad to be able to discuss the suggestion of Dr Bissett

There was a negative nitrogen balance in all patients because of septicaemia, and the median hospital prognostic index was 0·920. On the basis of these findings, total parenteral nutrition (TPN) was initiated in the early postoperative period. TPN may be expensive but does not cost as much as a life, even in the world's poorest countries It is required especially in patients whose hospital prognostic index is less than 1

We did not perform culture and sensitivity tests, but found that the combination of chloramphenicol, ampicillin/sulbactam and ornidazole was effective. Since 1993 we have also used ciprofloxacin and chloramphenicol at random in the treatment of typhoid enteric perforation. At present, we have not found any statistical differences between ciprofloxacin and chloramphenicol, though this study is still ongoing.

In a prospective study, four patients who died had been admitted to hospital in septic shock, and their perforation-to-operation interval was more than 3 (median 4) days.

Ultrasonographic carotid plaque morphology in predicting stroke risk

Sir
Each time we open a carotid artery containing soft haemorrhagic plaque, common sense tells us that this friable tissue must be a source of distal embolization and consequently a source for the cerebral symptoms encountered by our patients. We therefore find it relatively easy to be persuaded by the powerful arguments advanced for the role of haemorrhagic plaque in the development of cerebral symptoms put forward by Dr Geroulakos and colleagues (*Br J Surg* 1996; **83**: 582–7). However, the role of plaque type in the development of cerebral symptoms may be considerably more complex than the simple view that soft pieces of haemorrhagic material are becoming dislodged. There were some surprising findings in our own study of the role of carotid plaque morphology in the development of symptoms[1] based on a series of 4258 carotid arteries of all degrees of stenosis, 1342 of which were symptomatic and 1558 of which were identified as having characterizable plaque. We found that the two parameters of plaque morphology and degree of stenosis were very closely related and almost inseparable Thus at under 20 per cent stenosis 96 per cent of plaques were fibrous, whereas at more than 80 per cent stenosis 85 per cent of plaques were haemorrhagic. In addition, although type I haemorrhagic plaques are associated with more symptomatic vessels, it is impossible to attribute this finding simply to plaque type because all these vessels have a high degree of stenosis. It was our conclusion that plaque morphology did not add to the sensitivity of degree of stenosis in predicting the presence of symptoms

We also demonstrated that the only symptom that may be more likely to be associated with haemorrhagic plaque is amaurosis fugax. Therefore, studies of symptomatic patients that contain large numbers of patients with amaurosis fugax may be biased to finding more with type I plaque. The conclusions from these studies cannot therefore be translated to symptoms of other conditions such as transient ischaemic attacks or strokes.

In a further study (currently undergoing peer review), we have also shown that type I haemorrhagic plaque is three times more likely to be found in men. However, once again we did not find that this was translated into an increase in symptoms in men As the degree of carotid stenosis increases, so the type of plaque changes to a more haemorrhagic form This fact may well be the result of altered flow dynamics within the vessel creating shear stresses as a result of the Bernoulli effect[2] rather than any intrinsic change within the composition of the atheroma.

Although we would like to believe that soft haemorrhagic plaque is a marker for patients at high risk of stroke, we consider that it is no more than a marker of increased severity of generalized atherosclerosis, and as an indirect result will inevitably be associated with a higher number of strokes. This suggestion is illustrated by the fact that those with high-risk plaques are more likely to have a myocardial infarction or problems with peripheral vascular disease than they are to have cerebral ischaemic events[3].

We would agree with Dr Geroulakos and colleagues that the criteria for selection of high-risk patients for carotid surgery should be better defined. However, it is idealistic to believe that this can be achieved by looking simply at either the degree of stenosis or the plaque morphology in the internal carotid artery Working on the basis that at least two-thirds of patients with strokes have normal carotid arteries, we should assume that a much more complex series of physiological events is taking place leading to cerebral ischaemia.

Screening for colorectal cancer with an immunological faecal occult blood test: 2-year follow-up

Sir

Dr Robinson and colleagues (*Br J Surg* 1996; **83**: 500–1) suggest that faecal occult blood screening can be improved, but screening with guaiac-based tests has some potential shortcomings[1]. Although the benefit and effectiveness of such screening remains controversial, the mortality rate from colorectal cancer necessitates the revision of current policies and the development and introduction of new methods and markers.

Although more sensitive and human-specific immunological methods have been developed in recent years, these techniques are usually limited to the demonstration of haemoglobin in the faeces[2]. This practice has several inherent difficulties due to the degradation of haemoglobin and the irreversible binding of its major constituent to a special component of the faeces. Recently, some authors have proposed the parallel study of other blood proteins as well[3,4], since they are more stable in faeces than haemoglobin We wished to examine the potential advantages of parallel analysis of haemoglobin and albumin in faecal samples from young, healthy subjects and patients with verified colorectal carcinoma[5]. Our experiments showed that the parallel demonstration of the two proteins significantly enhanced the detectability of colorectal cancer. Therefore, further studies to demonstrate the efficacy of the method were carried out with screening of symptom-free individuals. The method does not require any dietary modification.

Our screening population included 4223 persons selected randomly with an approximately even proportion of both sexes. Mean age was 55 years The positivity ratio was 4·5 per cent and only those patients were referred for endoscopy. Colonic or rectal carcinoma was detected in nine patients (Dukes stage A, two; B, six; C, one) The youngest patient was a 39-year-old woman and the oldest an 80-year-old man. With the aid of antihuman haemoglobin immune serum alone, we could have detected only six carcinomas and overlooked three (Dukes stage A, one, B, two).

We are sure that the current form of mass faecal occult blood screening is indispensable, but its conditions should be modified. Naturally, efforts should be made to search for new and more potent biochemical and genetic markers and to test them in clinical practice.

Immune function early in acute pancreatitis

Sir

Messrs Widdison and Cunningham (*Br J Surg* 1996; **83**: 633–6) drew attention to lymphopenia in pancreatitis and suggested that it might be because of redistribution of lymphocytes from blood to other tissues rather than impaired immune function. Soo *et al.*[1] have provided evidence for this in patients with acute apendicitis. Their patients showed: (1) lymphopenia especially with severe sepsis; (2) CD4/CD8 ratios unchanged; (3) depletion of T cells affecting memory cells of phenotype CD45R0 while leaving in circulation naive cells of CD45RA phenotype, (4) accumulation of memory cells in the inflamed appendix; and (5) migration of memory cells from blood to appendix proved by sampling blood from both appendicular artery and vein. The T cells remaining in the blood were less reactive in proliferation assays than those in the inflamed (but not the normal) appendix. Selective cellular migration may thus explain the anergy of peripheral blood lymphocytes from septic patients.

Similar changes may occur in pancreatitis and other surgical disasters in which lymphopenia was described as long ago as 1952[2].

We have examined blood counts for all patients admitted under a general surgical service over 1 year in the hope of gaining some understanding of the pathology leading to lymphopenia (*Table 1*). If we are to postulate that sepsis was the sole or main determinant of lymphopenia, we shall have to accept that both pancreatitis and bowel obstruction presented a septic challenge. And what of 'assorted abscesses'? Were they too small to have an effect, or were they infected with the wrong sorts of bacteria? We agree with Messrs Widdison and

Table 1 Data for 644 patients who underwent general surgery

Diagnosis	No. of patients	Mean lymphocyte count* (× 10⁹/l)	95 per cent confidence interval
Hernia (elective operation)	109	1·83	1·63–2·03
Benign breast disease	20	1·71	1·50–1·92
Breast cancer	36	1·70	1·54–1·85
Assorted abscesses	36	1·70	1·30–2·10

'Residual' appendicitis following incomplete laparoscopic appendicectomy

Sir
With reference to the recent article by Messrs Milne and Bradbury (*Br J Surg* 1996; 83: 217) and the letter by Messrs Somerville and Lavelle (*Br J Surg* 1996; 83: 869) concerning incomplete removal of the appendix laparoscopically, we agree that recurrent appendicitis after appendicectomy is not peculiar to the laparoscopic approach. We are aware of a case of 'recurrent appendicitis' 10 years after open appendicectomy. A 32-year-old woman presented with clinical signs of infection and a painful induration around a 10-cm long old appendicectomy scar. At laparotomy, we found a growth of inflammatory and granulation tissue through the abdominal wall between caecum and the subcutaneous layer An ileocaecal resection was performed and the postoperative course was uneventful[1]. As the histological examination confirmed our suspicion, we believe that the appendicectomy 10 years previously did not remove the organ as completely as it should have.

Especially, but not exclusively, in the laparoscopic era we would like to emphasize the importance of careful identification of the appendix base and complete resection. A 'recurrent appendicitis' may occur after a short time, or very late after the first surgical procedure, as in our patient.

No obvious advantages for thoracoscopic two-stage oesophagectomy

Sir
I was interested to read the article by Mr Robertson and colleagues on the advantages and disadvantages of thoracoscopic oesophagectomy (*Br J Surg* 1996; 83: 675–8), but regret that they perpetuate the error of attributing the one-stage combined abdominal and right thoracic approach oesophagectomy solely to Ivor Lewis (not Ivor–Lewis (*sic*) as in their article). Lewis originally described an oesophagectomy in two stages, separated by an interval[1]. An initial laparotomy was performed preparing the stomach for subsequent repositioning and anastomosis in the chest 2 weeks later via a right thoracotomy. Norman Tanner independently originated a similar procedure, but in one stage[2], in the same year (1944) that Lewis initiated the two-stage operation. Tanner's publication, however, appeared 9 months after Ivor Lewis's contribution was published in this journal.

Incidentally, Norman Tanner was a good friend of Ivor Lewis and while I was Tanner's Registrar at St James, Balham, London in 1958, he performed a Billroth I gastrectomy on his friend for a benign gastric ulcer.

As the Tanner one-stage procedure is that which is in common use today, it would seem appropriate that the names of both these outstanding British surgeons be linked to the operation they independently pioneered, the Lewis–Tanner oesophagectomy.

Colonic decompression without on-table irrigation for obstructing left-sided colorectal tumours

Sir
We read with interest the article by Mr Nyam and colleagues concerning the intraoperative decompression of the obstructed left colon (*Br J Surg* 1996; 83: 786–7) and are in agreement that on-table colonic lavage is unnecessary in some instances. We have found that milking the bowel contents into the specimen before resection further reduces operating time and the risk of peritoneal contamination, and we would advocate this as a technique.

Thrombolysis for acute deep vein thrombosis

Sir
We enjoyed the paper by Armon and Hopkinson (*Br J Surg* 1996; 83: 580–1) on thrombolysis for deep vein thrombosis (DVT) and agree that this modality of treatment needs to be investigated further, and its effectiveness in preventing pulmonary embolism and chronic venous insufficiency needs to be established. We also agree that there needs to be strict selection criteria for patients receiving this treatment. Our comments relate to below-knee DVT which we believe merits different management.

Armon and Hopkinson suggest that untreated below-knee DVT results in a 30 per cent incidence of pulmonary embolism and that 20–40 per cent of these will be fatal (i.e. 6–12 per cent of patients with below-knee DVT will die from pulmonary embolism). Although there is a high incidence of episodes of silent pulmonary embolism in both above- and below-knee thromboses, anticoagulant therapy does not seem to affect the incidence of pulmonary embolism in patients with below-knee DVT[1]. Furthermore, clinically significant pulmonary embolism occurs only when the thrombus progresses proximally[2]. In a study on 90 patients who underwent screening duplex scans after operation, distal DVT was detected in ten patients (9·1 per cent). None of these (followed for 14 days with daily scans) manifested either symptomatic DVT or pulmonary embolism. The follow-up extended to 12 months[3]. In another study no demonstrable effect on progression of below-knee DVT in mobile patients wearing thrombo-embolic deterrent stockings (TEDS) and treated with phenylbutazone was seen compared with those wearing TEDS and treated with anticoagulant therapy[4]. Finally, thrombolysis is not without danger. Complications of internal and external bleeding, as well as the possibility of sending fresh showers of pulmonary emboli, must not be ignored.

We consider that below-knee DVT should be managed by serial duplex scanning and antiplatelet medication[3]. If proximal progression of thrombus is detected, the patient is treated with full anticoagulation. We also believe that, in studies on thrombolytic therapy in acute DVT, patients with below-knee DVT should be excluded.

Authors' reply

Sir

We are grateful for the comments of Messrs Shoab and Shami. At the risk of deflecting attention away from the bulk of our article by dealing with matters relating to the introductory paragraph, we would like to respond

We accept that the risk of pulmonary embolism from below-knee deep vein thrombosis (DVT) is small, when treated. However, untreated below-knee DVT can progress and the patient may therefore run the risk of fatal pulmonary embolism. Untreated pulmonary embolism has a high associated mortality rate and it is for this reason that we have quoted a figure of 20–40 per cent based on the work of Schulman[1] This is, of course, a difficult figure to prove or disprove due to ethical constraints. The only randomized study of no treatment *versus* heparin for pulmonary embolism in 1960 was stopped after five of 19 patients in the untreated group died from fatal pulmonary embolism[2]. Nielson's trial in the two papers cited compares two treatment options rather than anticoagulation *versus* no treatment.

We wish to emphasize that the main reason for advocating thrombolysis as a treatment option for acute DVT is not to prevent pulmonary embolism, a job done admirably by anticoagulation, but to prevent the post-thrombotic syndrome or chronic venous insufficiency Chrome venous insufficiency undoubtedly does occur following some below-knee DVTs, so we hesitate to rule these patients out entirely as candidates for a treatment that may confer long-term benefit. Only limited conclusions can be drawn from just ten screen-detected DVTs followed for only 12 months in Grady's study. Nevertheless, as stated in our article, we agree that invasive treatment, such as catheter-directed thrombolysis, should be concentrated on patients with more severe proximal DVT, as these patients have most to gain.

Conversion operation for alkaline reflux after total gastrectomy and Schloffer reconstruction

Letter 1

Sir

We agree with Dr Fass and colleagues (*Br J Surg* 1996, 83: 270–1) that alkaline reflux can often complicate a loop oesophagojejunal anastomosis after total gastrectomy, and were interested to read their technique of conversion to a Roux-en-Y loop. In 1988, we reported a similar method which involves application of a linear stapler (TA55; AutoSuture, Ascot, UK) across the afferent limb of the jejunal loop just above the enteroenterostomy[1]. The procedure is simple to perform and avoids the often difficult dissection under the diaphragm. We have used this technique on several occasions with good results and have recently encountered a patient who bears testament to its efficacy.

A 61-year-old man underwent total gastrectomy for an early gastric cancer with reconstruction by loop oesophagojejunal anastomosis and enteroenterostomy. He initially made an uncomplicated recovery but 1 year later presented with severe biliary reflux, confirmed on endoscopy. He therefore underwent the procedure described with complete resolution of his symptoms. Six months later he developed symptoms of both biliary colic (with gallstones confirmed on ultrasonography) and a recurrence of the biliary reflux. Laparotomy demonstrated not only cholelithiasis but that the staple line across the afferent loop had opened. Cholecystectomy was performed and the afferent limb was reoccluded with a stapling gun. On review 6 weeks later, all symptoms had resolved. We recommend this procedure as a quick, simple and effective alternative to the operation described by Dr Fass and colleagues.

Letter 2

Sir

We read with interest the excellent paper by Dr Fass and colleagues (*Br J Surg* 1996; 83. 270–1). May we comment briefly on a few aspects of this article? The vast majority of patients having so-called alkaline reflux oesophagitis and its consequences have had previous gastric and/or oesophageal operations that permit free flow of duodenal contents back into the oesophagus.

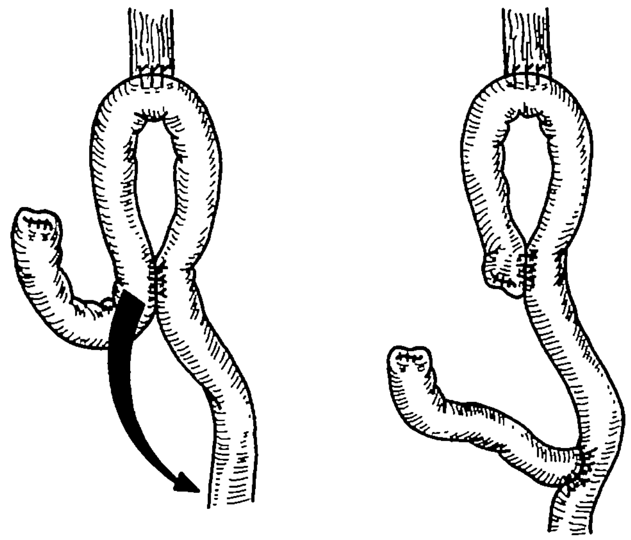

Fig 1 Schematic diagrams showing conversion operation for alkaline reflux after oesophagojejunostomy with entero-enterostomy

This pathological finding could make the life of patients completely unbearable. Adequate drug treatment is presently not available. Most of these patients require remedial surgery. Antireflux surgery with biliary diversion – as mentioned by the authors – has become the treatment of choice There are different possible surgical interventions and that choice should be guided by a complete understanding of the patient's symptoms and investigation of the underlying pathophysiological and anatomical abnormalities.

Until 1994, 35 reoperations were performed because of alkaline reflux oesophagitis in our department. In two cases, after total gastrectomy the operation was a loop oesophagojejunostomy. The solution was to perform a Roux-en-Y formation In six cases the previous operation was a loop oesophagojejunostomy of the Braun type. The enteroanastomosis was not sufficient to divert the duodenal content because of the effect of the isoperistaltic afferent loop. The afferent loop was transected below the level of the enteroenterostomy. So the anastomosis remained functional and an additional end-to-side enterostomy was performed. The length of the loop between the two anastomoses had to be more than 50 cm – as usual (*Fig. 1*) No patient died and the complaints resolved. Different examinations such as radiography, endoscopy and even hepatobiliary scintigraphy showed no pathological conditions.

The advantages of this solution are as follows. (1) Adhesions are frequent in the region of the oesophagojejunal anastomosis If the proposed solution is adopted it is not necessary to operate in this region which can be especially difficult if the anastomosis has been performed in the mediastinal space. (2) It is not necessary to perform a so-called ventral hemijejunoplication; we are not convinced that it has an antireflux effect The authors themselves mentioned that the main factor preventing reflux is a long Roux loop of at least 50 cm and in our opinion this in itself is enough.

Author's reply

Sir

We are very grateful for the great interest in our procedure demonstrated by two such expert letters describing interesting alternative methods of treating alkaline reflux after total gastrectomy and Schloffer reconstruction. Both methods, described by Messrs Grabham and Kelly, and Professor Kiss *et al.*, have in common that they more or less preserve the afferent loop of the previous Schloffer reconstruction. As Professor Kiss correctly mentioned, the isoperistaltic afferent loop of the Schloffer reconstruction is the cause of jejuno-oesophageal reflux, even if there is diversion by an enteroanastomosis. Considering data from the literature, the Roux loop would have to be 50 cm long below the old enteroanastomosis to achieve an effective prevention of ascending duodenal contents. We believe that in such a reconstruction the resorptive capacity of the small bowel would be restricted too much by the gastric substitution. Additionally, in Mr Grabham's procedure, the afferent loop acts as a blind loop. In the case described, this even led to the opening of a staple line We agree with Professor Kiss *et al.* that ventral hemijejunoplication is not mandatory to prevent reflux, but it helps to prevent a blind loop effect and construct a normal Roux-en-Y procedure.

In our experience the preparation of the anastomotic region is not problematic as long as the anastomosis is within the abdominal cavity and there is no history of an insufficiency. During dissection, mobilization of the left lobe of liver is generally an easy way of finding a previously untouched area close to the anastomosis

An evaluation of the POSSUM surgical scoring system

Sir

Mr Whiteley and colleagues complain that no details have been reported of how to apply the POSSUM system (*Br J Surg* 1996; 83· 812–15) despite many publications showing its application in surgical research and audit. It would appear, however, that their only concern is that they are unable to calculate the total number of predicted deaths from a group whose individual risks of death are determined from the POSSUM (Physiological and Operative Severity Score for the enUmeration of Morbidity and mortality) predictor equation for mortality Simply calculating mean risk is not a valid method of predicting the total number of deaths. The original POSSUM equations were based on the observed mortality and morbidity rates for all patients with scores above each particular level Therefore a minimum mortality rate of 1·08 per cent assumes that all patients with physiological scores above 12 and/or operative severity scores above 6 will have this overall risk of death. This rate is indeed the one seen worldwide. It should also be remembered that POSSUM is an audit aid and, as such, is not intended to be a perfect predictor of death or complication for an individual patient, but for a patient group.

Whiteley *et al.* also state that their sample was representative of the general surgical workload However, just over 5 per cent of their sample had a greater than 25 per cent risk of death. It only requires an elderly patient with an abnormal electrocardiogram to undergo elective surgery for intra-abdominal malignancy to provide a greater than 25 per cent mortality risk. This fact means that either the population of Portsmouth is very fit, they undergo only minor surgery, or, as is more likely, the sample was not representative and length of stay is not 'indicative of both the severity of the operation performed and the physiological state of the patient'. All non-day-case surgical patients should be included but they have not stated whether or not all emergency surgical procedures were included.

Authors' reply

Sir

We accept that the POSSUM physiological and operative scoring is described well enough in the literature to allow its application by independent investigators. However, to the best of our knowledge, this is not the case for the application of the predictor equations and the assessment of their goodness of fit to reported deaths.

In the absence of such guidance, we have utilized standard methods, well documented in the statistics literature, to assess the goodness of fit of both predictor equations[1–4]. It may be that Mr Copeland and co-workers use a different method of assessing the goodness of fit of their equation. However, in the absence of publication of their method, we are unable to comment on its relative validity. The Lemeshow–Hosmer methodology that we used produces an immediately meaningful comparison of predicted deaths with reported deaths, without having to resort to the complications and abstractions of receiver–operator characteristic curves and cut-off levels.

Messrs McIlroy and Copeland are incorrect in stating that 'simply calculating mean risk is not a valid method of predicting the total number of deaths'. Logistic regression is a form of discriminant analysis, which is intended to ascribe risks to individuals. It therefore follows that the sample population risk is the mean of the individual risks. Given that the risks can be applied to individuals, Mr Copeland's minimum risk of mortality of 1·08 per cent is too high a risk to ascribe to the fittest patients (physiological score 12) undergoing the most minor surgery (operative score 6). It may be that his method of analysis involves some extra stage or adjustment so that risks cannot be applied to individuals but only to the population above some arbitrary cut-off level, but this is not the case with our methodology.

POSSUM's usefulness as a research and audit tool lies in its ability to cope with differences in population and case mix between different surgeons and centres. If this is true it should not matter whether or not our sample population is fitter or is receiving relatively more minor surgery. We believe, however, that we presented reasonable evidence that our sample was representative of our general surgical workload at the time. We stated that day cases and paediatrics were excluded from our study. Emergency admissions were not excluded. Given that we used standard methods of analysis we would welcome publication of the method of analysis of Mr Copeland and co-workers.

Year Book of Surgery 1995

Roshan Lall Gupta. 227 × 148 mm. Pp. 224. Not illustrated. 1996. New Delhi: Jaypee Brothers Medical Publishers. Price unavailable.

The *Year Book of Surgery 1995* is a collection of surgical abstracts gleaned from 20 journals, ranging from *The British Journal of Surgery* to *Tropical Gastroenterology*. The aim is to help teachers, practising surgeons and postgraduate students 'reorient their clinical approach in the light of new trends'. The book has been published in 1996 but, inevitably, the abstracts that are quoted were published in 1994. In approximately 10 per cent of the abstracts the editor has added an interpretive personal footnote. The rest of the abstracts are simply reproduced from the original journals. At first sight it is easy to be somewhat disparaging of a book of this type. In the Western world we have become so familiar with access to computer-based literature searches that no surgical trainee would use a book of this type. In order to get a more balanced response to the book, I sought the opinion of one of our surgical registrars from Pakistan It is important to realize that this volume sells in the Indian subcontinent for 200 rupees which is the equivalent of UK £5.00. It is possible that it may be of use to some surgeons in training who are approaching the second part of a surgical fellowship examination and who do not have access to recent journals or the time to glean the important articles. Such a trainee might find this small textbook to be stimulating and of some interest. It is not, however, truly comprehensive in that there is very little in the way of paediatric, vascular or orthopaedic surgery. This text will not be purchased by trainees in the Western world but it may have a limited market in the Indian subcontinent.

Prostatic Outflow Obstruction: Clinical Investigation and Treatment

P. J. Shah (ed.). 250 × 175 mm. Pp. 174. Illustrated. 1995. Oxford: Blackwell Science. £49.50.

Transurethral resection of the prostate (TURP) has largely superseded open surgery for benign prostatic obstruction, but it still carries small and significant mortality and morbidity rates. Hence the search continues for less invasive treatments with fewer side-effects, which may be suitable for treating this common condition at an earlier stage in the disease process. This book discusses modern diagnostic techniques for assessing prostatic obstruction, and evaluates the many new therapies tried in recent years in pursuit of these goals. These range from medical management (e.g. α-adrenergic blockers), through minimally invasive therapies (such as microwave hyperthermia), to alternative surgical procedures using laser ablation of the prostate, balloon dilatation or prostatic stenting. Modifications to existing surgical techniques to render TURP safer are also discussed. The authors draw largely on personal experience of evaluating these techniques at the Institute of Urology in London, complemented by review of the literature. As this subject is rapidly changing, some of the techniques described have already failed to meet initial expectations, while others, including laser therapy, have been developed considerably further. Nevertheless, this volume succeeds in providing a comprehensive review of an important topic that will interest both the urological trainee and the practising urologist.

The Cambridge Dictionary of Statistics in the Medical Sciences

B. S. Everitt. 233 × 156 mm. Pp. 277. Illustrated. 1995 Cambridge: Cambridge University Press. £12.95.

This slim volume provides brief definitions of some 2000 statistical terms. I was consistently impressed by the precision of the definitions and had to look extremely hard to find examples to which I took exception. Even to browse through the dictionary is quite rewarding – I look forward to seeing articles in *The British Journal of Surgery* littered with 'sunflower plots' – and it does contain a thread of dry humour: 'Degrees of freedom (df): An elusive concept that occurs throughout statistics. Essentially, . . .'. The selection of entries for a dictionary is highly subjective and the author's selections appear to reflect more of an interest in statistical analysis than in the design or conduct of clinical trials. For example, there are several entries on minor aspects of analysis of variance (e.g. Mauchly's test), but no mention of numbers needed to treat, good clinical (research) practice, or standard operating procedures. If this dictionary has a weakness, it is that the definitions themselves often assume a fair degree of understanding of statistical concepts, I can see some clinicians locked into ever-decreasing circles as they follow up cross-references trying to understand the definition of the definition of the term where they started. I do not think that I could regard this as a 'must have' for all active clinical researchers However, anyone involved in refereeing or editing medical manuscripts will find it invaluable, saving hours by throwing immediate light on to unfamiliar statistical terms.

Urology. 2nd ed.

J Blandy and C. Fowler. 282 × 220 mm Pp. 639. Illustrated. 1995. Oxford: Blackwell Science. £99.50.

It is a remarkable achievement for two authors to write a well referenced textbook of 633 pages covering the whole of urology, which is both up to date and easily readable; Blandy and Fowler have succeeded admirably. The volume is a second edition which is aimed at the young urologist starting out on his or her specialist training. It assumes nothing and starts at the beginning, with the first chapter on the armamentarium available to the urological surgeon today. Urological endoscopes, diathermy machines, lasers and lithotriptors are all described with helpful diagrams. Subsequent chapters look at the kidney, bladder, prostate, urethra and penis, testicle and adrenal. Each chapter is split into anatomy and physiology, followed by the disease processes that occur in the relevant organ There are a few criticisms. Although very well illustrated (in black and white) some of the radiographs are of poor quality and, occasionally, authoritative statements are made which are unsubstantiated. However, neither of these criticisms takes much away from a book that urological trainees will find immensely helpful.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles Short notes, case reports and surgical workshops are also accepted. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** In order to avoid subsequent embarrassment, authors are requested to submit with their manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that publications or submissions using the same data set should be submitted to the Editors to allow assessment of any potential overlap with the submission to the Journal. The title page should indicate whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Authors are requested to send three copies of original articles and other editorial matter to: The Senior Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone 0171 404 4101. Facsimile· 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. The covering letter should state whether an abstract of the work has been published and an appropriate reference should be given on the title page. Authors must disclose in the covering letter any potential or actual personal, political or financial interest they may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editor. Sources of financial support for the work should also be acknowledged. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994, 308: 39–42). When a paper has many authors, they may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; 345: 668).

Following final approval of articles, authors are asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known **Do not justify.** Particular attention should be taken to ensure that any articles submitted adhere **exactly** to Journal style in all respects. Please send us digital versions of your figures. Ideally, these should be sent in native format or PICT if created on a Mac, or in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential to the understanding of the figure, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors

Rejected manuscripts and illustrations will not be returned to the authors, unless this is specifically requested.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Evidence of such consent should be submitted with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; 296: 401–5 or the *Annals of Internal Medicine* 1988; 108 258–65, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses **When quoting specific materials, equipment and proprietary drugs, authors must state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript should contain a summary of no more than 150 words on a separate page. Authors are reminded that there is considerable pressure on editorial space in the Journal Lengthy manuscripts are likely to be returned to authors for shortening. The discussion in particular should be clear and concise, and should be limited to matters arising directly from the results. Authors should avoid discursive speculation. **Randomized controlled trials** should be clearly identified as such in the title and summary.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem The author of each accepted review will receive an honorarium. Potential authors seeking advice on the suitability of review topics are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK

Leading articles

The Editors commission signed leading articles to *The British Journal of Surgery*. These articles are 600–1000 words in length, address controversial topics of current interest and are supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Short notes

These are original observations presented in brief form. They should follow the standard format of introduction, methods, results and discussion, but no summary is required. Short notes should not exceed 500 words with a maximum of five references and one table or one figure.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is high. Case reports should be no more than 400 words (300 if accompanied by a figure), with no more than five references and one illustration.

Surgical workshops

These describe technical innovations or modifications that may be useful in surgical practice. These articles should be less than 500 words long; they may be accompanied by no more than two figures and up to five references.

Typescripts

It is *essential* that manuscripts be clearly reproduced with adequate space for editorial notes. **Papers must be typewritten or printed on A4 paper (210 × 297 mm) on one side of the paper only with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to the authors for recasting.** Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations. The text should usually follow the standard sequence of introduction, methods, results and discussion. These sections should run sequentially through the text, avoiding blank space between them.

Title page

The title page should give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support, and (6) the category in which the manuscript is being submitted (original article, case report etc.).

Summary

The second page of the manuscript should carry a summary of not more than 150 words. This should clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. It should embody the purposes of the study or investigation, basic procedures (study material, and observational and analytical methods), main findings (with specific data and their statistical significance) and the principal conclusions. The summary should be written in clear prose.

Tables and illustrations

Three copies of all illustrations and tables should be submitted. Each table with an appropriate brief title should be typed on a separate page. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Radiographs, photomicrographs, etc should be submitted in the form of glossy prints, original transparencies or negatives and should not be mounted. Photocopies should be of sufficient quality to enable the Journal's referees to judge their content and value. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s), the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work the original source must be given in full. Permission to use published work must be obtained from the original author and the publisher before submission.

Abbreviations

Authors should limit the use of abbreviations. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Abbreviations should be used consistently throughout the text and must be clearly defined on first use.

Numbers and units

The decimal point, not a comma, is used, e.g. 5·7. A space and not a comma follows thousands and multiples thereof, e.g. 10 000. SI units (International System of Units) should be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points

References

References should be typed with double spacing and cited in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged; reference to unpublished communications is not acceptable. Personal communications should be cited in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, references should be numbered consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

Statistics

For detailed guidance on the handling of statistical material, authors should consult *Br J Surg* 1991; 78: 782–4. The Editors and statistical referees in evaluating a manuscript will consider the *design* of the study, the *presentation* of data, the *analysis* of data and the *interpretation* of results.

Design

Authors should set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen endpoints, and explain the rationale for the choice of sample size.

Presentation

Whenever possible a graphical presentation should be used to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Use of the '±' symbol should be avoided; these statistics should be presented in parentheses after the mean value.

Analysis

There should be a clear description of which methods were used for which analyses, and any methods not in common usage should be supported by references. Results of statistical tests should be reported by stating the value of the test statistic, the number of degrees of freedom and the P value For example, '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$' might be reported. Actual P values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Statistical significance should not be confused with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Authors should beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

Clinical Radiology

A Journal of the Royal College of Radiologists

Editor: **R H Reznek**, St Bartholomew's Hospital, London, UK.

Clinical Radiology is an international journal publishing original research, editorials, review articles and case reports on all aspects of diagnostic imaging, including radiotherapy, interventional radiology, nuclear medicine, drugs in relation to radiotherapy in cancer patients and the newer techniques of computed tomography, ultra sonography, digital radiology and magnetic resonance imaging. Papers on radiological protection, quality assurance, audit in radiology and matters relating to radiological training and education are included. In addition, each issue contains correspondence, book reviews and notices of forthcoming events.

1996 SUBSCRIPTION INFORMATION

Clinical Radiology (ISSN 0009-9260) is published monthly. All subscriptions are entered on a calendar-year basis, beginning in January and expiring the following December. Back issues are available, please contact us for details. Subscription rates for Volume 51 (1996) are:

	Europe	**USA & Canada**	**Rest of World**
Institutions	£162.00	US$287.00	£178.00

British Journal of
UROLOGY

The Official Journal of the British Association of Urological Surgeons and Official Journal of the European Society of Paediatric Urology

Editor: *Hugh Whitfield*
Co-editor: *Bill Hendry*

The *British Journal of Urology*, now entering its 67th year of publication, is one of the most highly respected medical journals in the world. It presents unparalleled coverage of contemporary urological opinion, clinical reports and studies, innovations and developments.

Every issue gives invaluable practical information...
- primary papers
- review articles
- case reports
- basic science articles
- reports of meetings and BAUS reports
- correspondence and book reviews

The Journal is covered by Colleague (online), Current Awareness in Biological sciences, Current Contents, Current Clinical Cancer, Excerpta Medica, Biological Abstracts, UMI (Microfilms), BRS Colleague (full text), Chemical Abstracts, Modern Medicine, Index Medicus, NMLUIS Reference Up Date and UMI (Disk).

Atlas of Surgical Oncology

Edited by: ***John H Donohue, Jon A van Heerden** and **John R T Monson***

Atlas of Surgical Oncology describes, in detail, the techniques required to perform a wide range of named operations. In addition to the majority of common procedures, approaches to some of the rarer conditions are illustrated in detail.

Atlas of Surgical Oncology.....

- **contains contributions from a team of internationally-acclaimed experts in their field**
- **provides a wide-ranging overview of surgical techniques as practised by recognised experts in the field of surgical oncology**
- **reflects ongoing developments within surgery and in other disciplines, including traditional fields such as medical and radiation oncology, as well as new areas by study such as molecular biology and immunology**
- **considers the application of minimally invasive surgery in the treatment of cancer patients**
- **contains extensive, high-quality illustrations**

336 pages, 531 illustrations, hardback, 1994, 0-86542-422-5, £95.00

Order Form

Please fill in and return to Lucy Brodie at the address to the left.

☐ Please send me ______ copy/ies of **Donohue: Atlas of Surgical Oncology** @ £95.00 + pp (£1.75 UK; £3.00 Europe; £5.00 ROW)

☐ I enclose a cheque for £ .... made payable to Marston Book Services Ltd

☐ I wish to pay by Access/VISA/Mastercard/Diners Card/Eurocard/American Express with the sum of £ ....

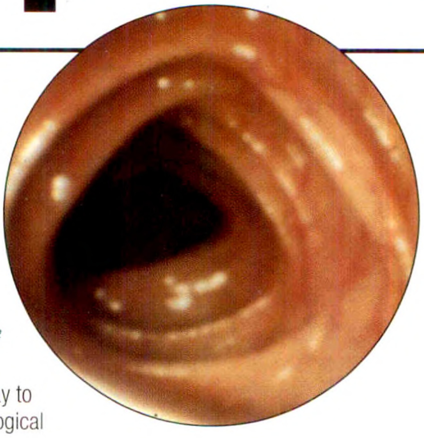
FOR EFFECTIVE BOWEL CLEANSING

W AVAILABLE
IN THE UK

Trials show nothing comes cleaner[1,2] than Phospho-soda™



"Phospho-soda was graded as 'excellent' or 'good' in 86% of 21 cases for the quality of mechanical bowel preparation, compared with 63% of 19 cases for sodium picosulphate"[1]

"Overall, endoscopists scored sodium phosphate as 'excellent' or 'good' in 90% vs. 68% after the polyethylene glycol lavage."[2]

Fleet Phospho-soda gives you a thoroughly effective way to clean the colon before colonoscopy examination, radiological procedures or surgery.

Fleet Phospho-soda is an oral saline laxative, increasing fluid accumulation in the lumen by osmosis to give bowel movements in 1/2-6 hours.

Under clinical conditions, not only did Fleet Phospho-soda outperform sodium picosulphate in bowel cleansing, it was also associated with less abdominal pain in the patients taking it. In addition, with a total dosage of only 90ml, patients found it easier to complete the course when compared with other bowel cleansing preparations.

The trials tell the story again and again – when you require a really clean bowel for medical procedures, you want nothing less than Fleet Phospho-soda.

Fleet™
Phospho-soda™
Oral Solution For Bowel Cleansing

scribing Information:
cations: For use as a purgative for bowel cleansing in preparation for surgery or preparing the colon for x-ray or endoscopic examination. **Active Ingredients:** Each 45ml bottle (Dosage 2 x 45ml) ains the equivalent of 24.4g (54.3% w/v) Sodium Dihydrogen Phosphate Dihydrate Ph Eur and 10.8g (24.0% w/v) Disodium Phospate Dodecahydrate Ph Eur per 45ml. Sodium content is 5.0g per 45ml. pients: Glycerol, Sodium Saccharin, Sodium Benzoate (E211), Ginger-Lemon flavouring, Purified water. Fleet™ Phospho-soda™ is sugar-free. **Dosage: Adults only:** Unless directed by a physician, Fleet spho-soda should be taken in the morning and in the evening on the day before examination or surgery. **Note: No solid foods may be taken for breakfast, lunch or evening meal on the day of ng this medicine. The liquid "diet" indicated should be strictly adhered to.** ***1st Dose*** *– At 7 a.m. (morning) on the day before examination or surgery:* Dilute total contents of one bottle (45ml) in a glass (120ml) of cool water. Drink this solution, followed by one full glass (240ml) of cool water. At mid-day, follow with at least three full glasses (720ml) of water or "clear liquid", more if desired. "Clear ds" include water, clear soup, strained fruit juices without pulp, black tea or black coffee, clear carbonated and non-carbonated soft drinks. ***2nd Dose*** *– At 7 p.m. (evening) on the day before examination or ery:* Dilute total contents of the second bottle (45ml) in half a glass (120ml) of cool water. Drink this solution followed by one full glass (240ml) of cool water. Additional "clear liquid" may be taken up until ight if necessary. This product normally produces a bowel movement in 1/2 to 6 hours. **NOT TO BE GIVEN TO CHILDREN. DO NOT USE** when nausea, vomiting or abdominal pain is present, unless directed by physician. **Contra Indications:** This product is contra indicated in patients with known or suspected gastrointestinal obstruction or ileus. Do not use in patients with congestive heart failure, chsprung's Disease or congenital megacolon. **Warnings:** Use with caution in patients with impaired renal function, heart disease, colostomy or on a low salt diet as hyperphosphataemia, hypocalcaemia, rnatraemic dehydration and acidosis may occur. Patients should be warned to expect frequent, liquid stools. **Interactions:** Use with caution in patients taking calcium channel blockers, diuretics, lithium ment or other medication that might affect electrolyte levels as hyperphosphataemia, hypocalcaemia, hypernatraemic dehydration and acidosis may occur. **Use in Pregnancy and Lactation:** Use under ical supervision only. **KEEP OUT OF REACH OF CHILDREN. Full prescribing information is available on request. Pharmaceutical Precautions:** Store below 25°C. Do not refrigerate. **Legal gory:** P. **Package Quantities:** Two single dose bottles, each containing 45ml of solution in a single carton. **Product Licence Number:** 0083/0044. **Product Licence Holder: E.C. De Witt & Co. Ltd., ubsidiary of C.B. Fleet Company, Inc. U.S.A.** For further information please contact the Marketing Department at the address below. Fleet™ Phospho-soda™ (2 x 45ml) N.H.S. Price £4.79.

Haemostasis
by tube

SURGICEL NU-KNIT* Absorbable Haemostat is designe
specifically for laparoscopy. Its double density gives extr
strength and integrity so that after passing through a cannul
it will unfold easily, ready for positioning on the bleeding site

As well as providing express delivery, it acts faster at th
bleeding site than traditional SURGICEL* Haemostat
saving valuable minutes of operating time
Also, left *in situ*, it offers reassurance o
continuing haemostasis beyond the
tamponade effect of surger
while it is absorbe
over the followin
7 to 14 days

SURGICEL NU-KNIT*
ABSORBABLE HAEMOSTAT
first choice for atraumatic
laparoscopic haemostasis

Product Licence PL5416/0005

SURGICEL NU-KNIT* Abbreviated Prescribing Information

Presentation Supplied as sterile pieces of creamy-white knitted textured fabric. **Uses** Adjunctively in surgical procedures to assist in the control of capillary, venous and small arterial bleeding.
Dosage and Administration Cut to size and apply directly to the bleeding surface with pressure. May be left in situ when it is absorbed within 7-14 days.
Contra-indications and Warnings Only the amount necessary to achieve haemostasis should be used. Remove any excess before surgical closure in order to facilitate absorption and minimise the possibility of foreig body reactions. In urological procedures, minimal amounts of material should be used and care must be exercised to prevent plugging of the urethra, ureter or a catheter by dislodging portions of the product. Avoid infected or contaminated wounds but if used the product must be removed prior to closure. Do not over-pack. Used in fractures or laminectomies, it must be removed as there may be interference with bone regeneratic It should not be used on non-haemorrhagic serous oozing surfaces.It should not be used around the optic nerve and chiasma and must be removed from other neural pathways. Should not be impregnated with an infective agents or with other materials such as buffering or haemostatic substances. Absorption could be prevented in chemically cauterised areas. If used as a wrap during vascular surgery, do not apply too tight Safety of use in pregnancy and lactation has not been established. However, the product has been in wide use for 30 years without any evidence of apparent hazard. There is no evidence that the product or breakdown products would have an effect on the foetus or on lactation.
Pharmaceutical Precautions Store under cool conditions, under 15°C. **Shelf Life** 5 years. **Legal Category** Not applicable

FORMATION
ations: Tazocin is a broad spec-
bactericidal penicillin for the
tment of the following infections
ed by sensitive bacteria:- lower
iratory tract infections, urinary
infections, intra-abdominal infec-
s, skin infections, septicaemia and
microbic intra-abdominal, skin and
er respiratory tract infections;
ents with impaired host defences.
age (intravenous use only):
lts/elderly/children over 12:
ally 4.5g every 8 hours (range from
-4.5g every 6-8 hours dependent
he severity). *Children:* No data to
port use. *Renal Impairment:*
ing reduction may be necessary,
se consult data sheet. Contra-
cations: Hypersensitivity to peni-
n, cephalosporin or ß-lactamase
bitors. Warnings: Discontinue if
phylactic or allergic reaction
rs. Precautions: Periodic assess-
t of renal, hepatic and haemato-
cal function advised. Discontinue
bleeding manifestations occur.
stant bacteria may cause superin-
ion. Convulsions may occur with
er than recommended doses.
sibility of hypokalaemia in patients
low potassium or on cytotoxics or
etics. Evaluate patients for
ilis prior to treatment for gonor-
a. Use during pregnancy or lacta-
: Only if benefit outweighs risk.
-effects: Most frequent: gastro-
stinal disturbances; various skin
tions including rashes, erythema,
itus and urticaria; allergic reac-
s; superinfection; phlebitis, throm-
hlebitis, pain/inflammation at site
njection. Less frequent: muscle
or weakness; hallucination; dry
th; stomatitis, sweating; oedema;
dness and rarely leucopenia, inter-
al nephritis. Haematological
nges, increases in liver and rarely
l function test values have been
rted. Overdose: Piperacillin may
educed by dialysis. Presentation:
cin 2.25g: Vials containing
racillin 2g (as piperacillin sodium)
tazobactam 250mg (as tazobactam
um). Tazocin 4.5g: Vials containing
racillin 4g (as piperacillin sodium)
tazobactam 500mg (as tazobactam
um). Basic NHS Price: 4.5g

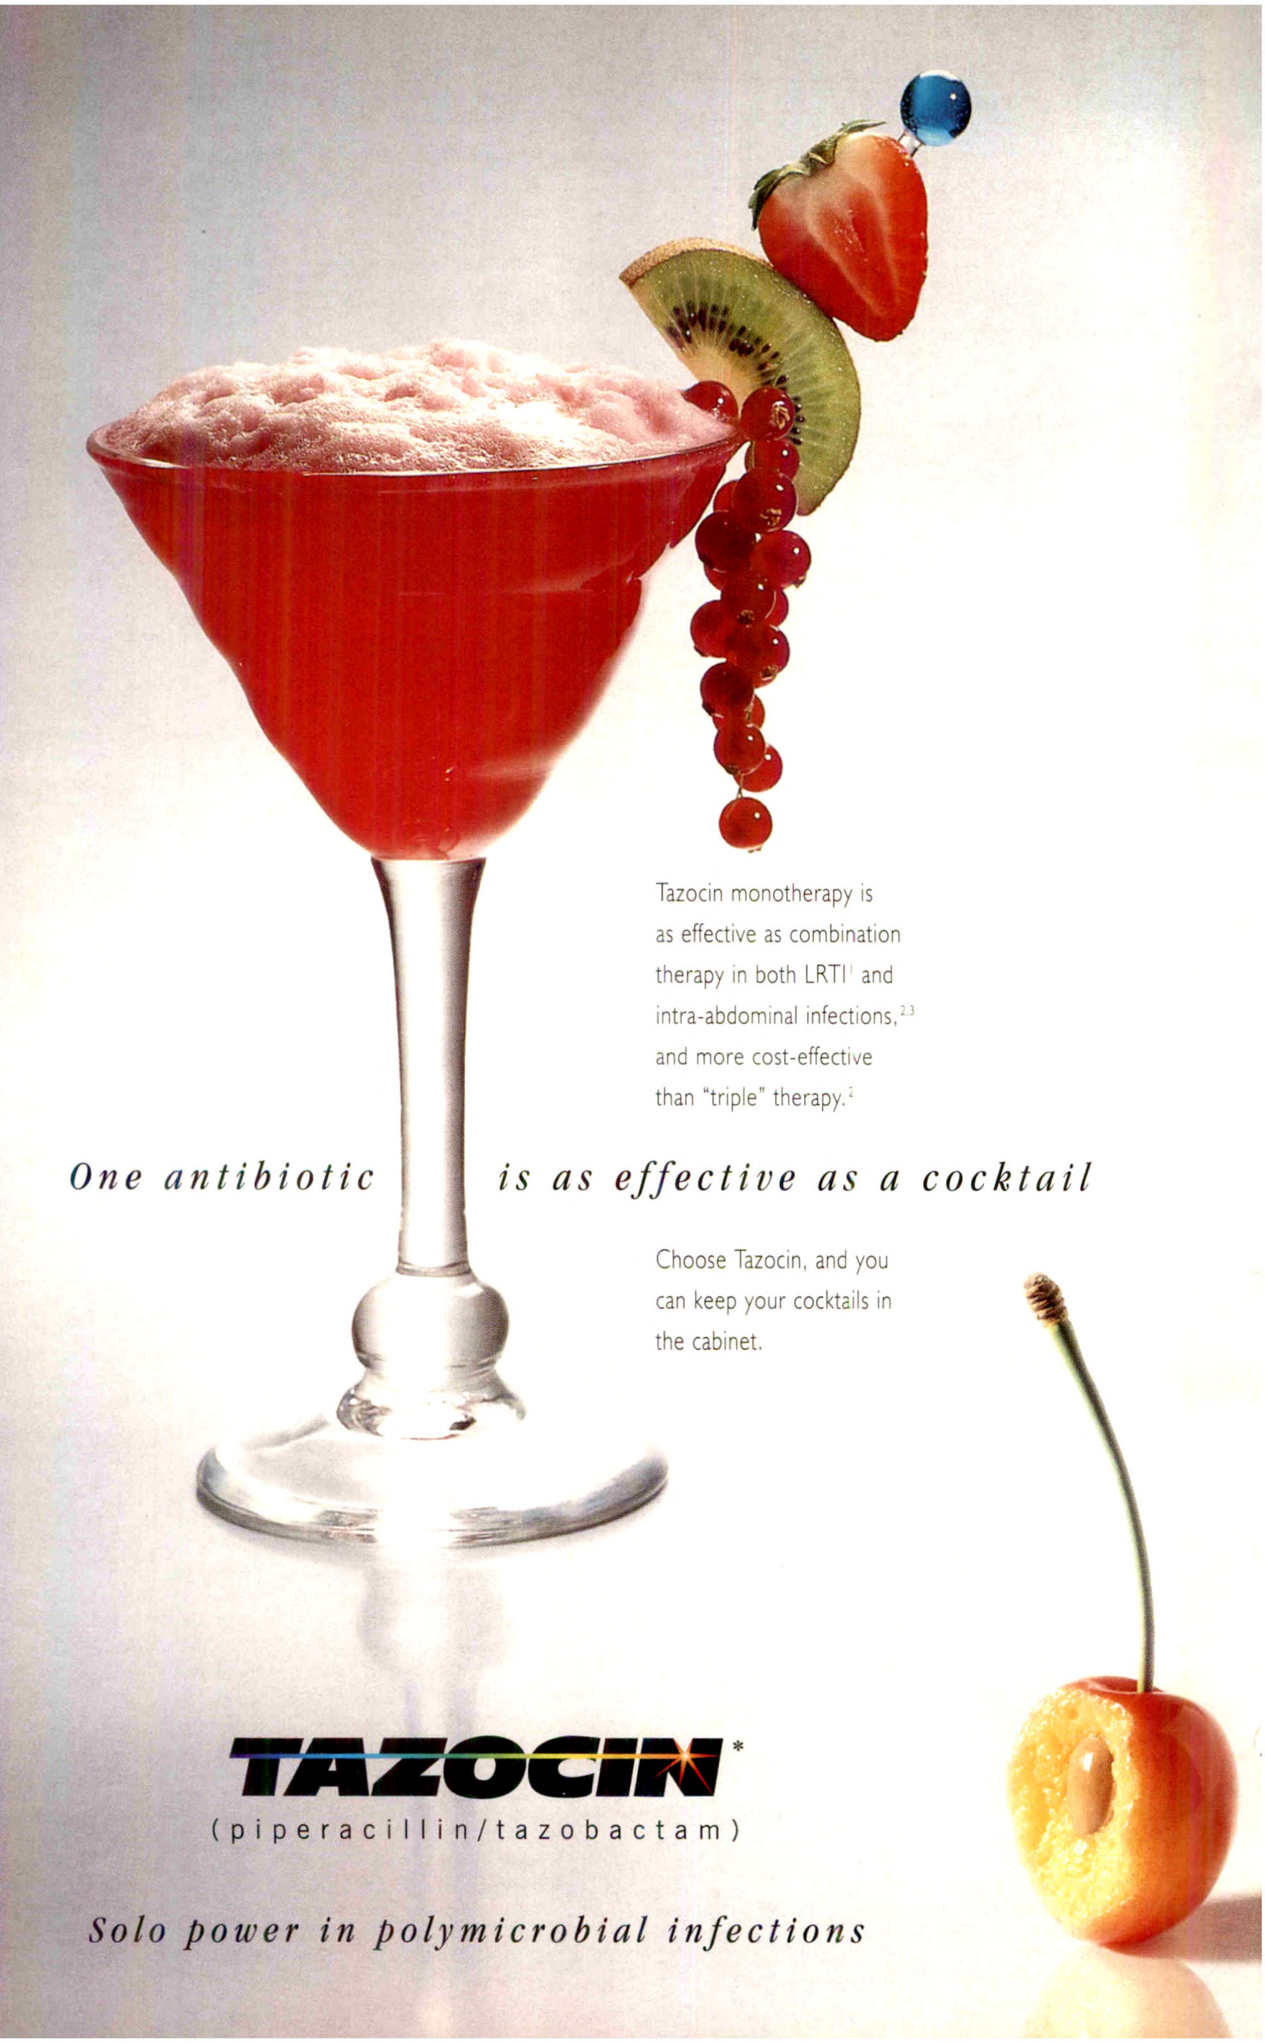
Vyeth

Lederle



Tazocin monotherapy is as effective as combination therapy in both LRTI[1] and intra-abdominal infections,[2,3] and more cost-effective than "triple" therapy.[2]

One antibiotic is as effective as a cocktail

Choose Tazocin, and you can keep your cocktails in the cabinet.

TAZOCIN*
(piperacillin/tazobactam)

Solo power in polymicrobial infections

The British Journal of Surgery

The Journal is specially related with the Association of Surgeons of Great Britain and Ireland and the Surgical Research Society

VOLUME 83 NUMBER 11 NOVEMBER 1996

Contents

1489 **Change of Chairman**
R. C. G. Russell and R. C. N. Williamson

Leading articles

1490 **Technique of hepatectomy**
S. T. Fan
Continued refinement has dramatically reduced the mortality rate associated with this procedure

1492 **The venous perforator**
C. V. Ruckley and K. R. Makhdoomi
The relationship between incompetent perforating veins and chronic venous insufficiency is poorly understood

Reviews

1494 **Desmoids in familial adenomatous polyposis**
S. K. Clark and R. K. S. Phillips
Desmoid disease affects about 10 per cent of those with familial adenomatous polyposis; intra-abdominal tumours are a particularly serious problem

1505 **Abdominal wounds in war**
R. Coupland
A desire to provide urgent surgery must not preclude competent surgical care

Original articles

1512 **Laparoscopic ultrasonography during cholecystectomy**
M. A. Röthlin, O. Schöb, R. Schlumpf and F. Largiadèr
This promises to become the method of choice for detection of duct stones

1517 **A Western surgical experience of peripheral cholangiocarcinoma**
S. V. Berdah, J. R. Delpero, S. Garcia, J. Hardwigsen and Y. P. Le Treut
Conventional hepatic resection is the only feasible treatment for this condition

1522 **Surgery for biliary obstruction by tumour thrombus in primary liver cancer**
B. Tantawi, D. Cherqui, J. Tran van Nhieu, M. Kracht and P. L. Fagniez
Rarely, jaundice in patients with hepatocellular carcinoma may be due to tumour thrombus within bile ducts, a situation where surgery is beneficial

1526 **One hundred and fifty hepatic resections: evolution of technique towards bloodless surgery**
M. Rees, G. Plant, J. Wells and S. Bygrave
A safe and well tried technique

1530 **Successful use of size-mismatched liver allografts in children by delayed primary closure of the abdominal wall**
A. S. Soin, P. J. Friend, G. Noble-Jamieson, C. J. E. Watson, N. V. Jamieson, R. Y. Calne and N. Barnes
A useful trick whilst awaiting the oversized liver to shrink in paediatric liver recipients

1532 **Randomized comparison of the neuroendocrine response to laparoscopic cholecystectomy using either conventional or abdominal wall lift techniques**
A.-M. Koivusalo, I. Kellokumpu, M. Scheinin, I. Tikkanen, L. Halme and L. Lindgren
The reduced neuroendocrine response seen with the abdominal wall lift method might benefit patients with poor renal function who require cholecystectomy

1537 **Alterations in intestinal function in acute pancreatitis in an experimental model**
X. D. Wang, Q. Wang, R. Andersson and I. Ihse
Permeability changes may be related to oxygen derived free radicals

1543 **Laparoscopic cholecystectomy in a patient receiving continuous ambulatory peritoneal dialysis** (case report)
A. M. Lale, T. J. Wheatley and M. L. Nicholson
The indwelling dialysis catheter simplified the creation of a pneumoperitoneum

Original articles (continued)

1544 **Audit of general practitioner referrals to a surgical assessment unit: new methods to improve the efficiency of the acute surgical service**
K. A. Dookeran, I. Bain and V. Moshakis
Early expert assessment can reduce admissions

1547 **Solitary caecal diverticulum strangulated in a femoral hernia** (case report)
R. M. Naunton-Morgan and A. Maw
A reminder that a hernia sac can contain almost any anatomical structure within the abdomen

1548 **Comparison of the cost of preventing postoperative deep vein thrombosis with either unfractionated or low molecular weight heparin**
D. Bergqvist, B. Lindgren and T. Mätzsch
Routine prophylaxis with either is cost-effective in general surgery and orthopaedic patients

1552 **Videoscopic subfascial incompetent perforator vein ablation** (surgical workshop)
A. R. J. Phillips and J. M. Fleischl
Minimally invasive perforator disruption is described

1553 **Knee-length *versus* thigh-length graduated compression stockings in the prevention of deep vein thrombosis** (short note)
A. M. Williams, P. R. Davies, D. I. S. Sweetnam, G. Harper, R. Pusey and C. D. R. Lightowler
The authors advocate the use of knee-length stockings

1554 **Pedal bypass for limb-threatening ischaemia: an 11-year review**
H.-H. Eckstein, H. Schumacher, N. Maeder, S. Post, Th. Hupp and J.-R. Allenberg
Provides limb salvage until death in two-thirds of patients

1558 **Rectus sheath bupivacaine analgesia after aortic surgery** (surgical workshop)
P. Curley, A. Grainger, G. C. Last and J. M. D. Galloway
A useful idea that requires formal comparison with epidural analgesia

1559 **Prospective randomized trial comparing sequential avulsion with stripping of the long saphenous vein**
B. Khan, S. Khan, M. G. Greaney and S. D. Blair
Sequential avulsion causes less pain and bruising

1563 **Prospective randomized trial comparing postoperative pain and return to physical activity after transabdominal preperitoneal, total preperitoneal or Shouldice technique for inguinal hernia repair**
P. Schrenk, R. Woisetschläger, R. Rieger and W. Wayand
No significant benefit found from laparoscopic techniques

1567 **Ethical implications of recognizing nutritional support as a medical therapy** (for debate)
J. MacFie
Medical ethics can be applied to nutritional support

1569 **Fast-to-slow muscle conversion by chronic electrostimulation: effects on mitochondrial respiratory chain function with possible implications for the gracilis neosphincter procedure**
D. F. Altomare, D. Boffoli, S. C. Scacco, M. Rinaldi, R. Vicente-Prieta, E. Martinelli and V. Memeo
A study providing a practical basis for optimizing fatigue resistance in gracilis neosphincters

1574 **Pouch-related fistula following restorative proctocolectomy**
F. Paye, C. Penna, L. Chiche, E. Tiret, P. Frileux and R. Parc
Experience in the management of pouch-related fistulas supports an aggressive surgical approach by repeat pouch–anal anastomosis

1578 **Results after restorative proctocolectomy and ileal pouch–anal anastomosis in patients with familial adenomatous polyposis and coexisting colorectal cancer**
Y. Ziv, J. M. Church, J. R. Oakley, E. McGannon, T. K. Schroeder and V. F. Fazio
Restorative proctocolectomy is feasible and may be curative

1581 **Resection of an end-colostomy stricture with a circular stapling device** (surgical workshop)
J. M. Ramia, A. Ibarra and J. Alcalde

Original articles (continued)

1582 **Biomechanical stabilization of the nipple valve in continent ileostomy**
K. W. Ecker, U. Hildebrandt, M. Haberer and G. Feifel
An interesting technique in preventing nipple failure in continent ileostomy reservoir

1586 **Problems in diagnosis and management of goitre in childhood and adolescence**
A. J. Webb, S. Brewster and D. Newington
Sage discussion about a surgical problem in children

1591 **Reduced collagen accumulation after major surgery**
L. N. Jorgensen, F. Kallehave, T. Karlsmark and F. Gottrup
Evidence for an *in vivo*, detrimental effect of major operations, and corticosteroids in patients undergoing major surgery, particularly when postoperative sepsis supervenes

1595 **D_2 gastrectomy: lessons from a prospective audit of the learning curve**
D. Parikh, M. Johnson, L. Chagla, D. Lowe and P. McCulloch
Results improve with time and training

1599 **Double Y–V plasty for postsurgical anal stricture** (case report)
B. Neelakandan
This report describes good results in two patients

1600 **Prognostic significance of lymph node metastasis in advanced carcinoma of the stomach**
S. J. Kwon and G. S. Kim
Ratio of involved : total lymph nodes has prognostic value

1604 **Prognostic significance of lymph node dissection in gastric cancer**
G. de Manzoni, G. Verlato, A. Guglielmi, E. Laterza, M. Genna and C. Cordiano
Extended node dissection may improve survival

1608 **Decreased E-cadherin expression is associated with haematogenous recurrence and poor prognosis in patients with squamous cell carcinoma of the oesophagus**
S. Tamura, H. Shiozaki, M. Miyata, T. Kadowaki, M. Inoue, S. Matsui, T. Iwazawa, T. Takayama, M. Takeichi and M. Monden
Failure to express E-cadherin is a marker of poor prognosis in oesophageal squamous cancer

1614 **Gastric tonometry and drain amylase analysis in the detection of cervical oesophagogastric leakage** (short note)
A. Machens, C. Busch, Hw. Bause and J. R. Izbicki
A practical procedure that complements radiological detection of oesophagogastric anastomotic leaks

1616 **Experimental oesophagogastric anastomosis: preliminary report of a new compression device that also fragments**
C. Rebuffat, R. Rosati, U. Fumagalli, F. Varoli, G. Roviaro and A. Peracchia
An ingenious device

1620 **Salvage treatment for inoperable neck nodes in head and neck cancer using combined iridium-192 brachytherapy and surgical reconstruction**
P. G. S. Cornes, H. J. Cox, P. R. Rhys-Evans, N. M. Breach and J. M. Henk
Combined therapy with brachytherapy followed by resection provides local control of disease in 62 per cent of patients with previously treated recurrent neck nodes in patients with head and neck cancer

ST BARTHOLOMEW'S AND THE ROYAL LONDON SCHOOL OF MEDICINE AND DENTISTRY

THE ROYAL HOSPITALS NHS TRUST

BREAST UNIT AT ST BARTHOLOMEW'S HOSPITAL

Surgical Research Fellow

A Post Fellowship Trainee in Surgery is required to pursue a research project evaluating a novel receptor in human breast cancer. The project is based primarily at St Bartholomew's Hospital with some work within the Department of Biochemistry at Queen Mary and Westfield College.

The Research Fellow will have the opportunity to participate in all of the clinical, research and training activities of this progressive Breast Unit although clinical duties are not expected to be onerous. The post is funded for two years.

Honorary Lecturer status has been applied for at St Bartholomew's, The Royal London Hospital and Queen Mary and Westfield Medical College.

It is expected that a higher degree will be presented towards the end of the Fellowship.

Further information regarding the position can be obtained by contacting Mr R Carpenter, Director of the Breast Unit on 0171 601 7032.

For further information and an Application Form please contact our 24 hour recruitment line on 0171-975 5171 quoting Reference: 96657. Your application is to be returned by 29 November 1996 and should be addressed to the Personnel Administrator, Queen Mary and Westfield College, Mile End Road, London E1 4NS.

UNIVERSITY OF LONDON

WORKING TOWARDS EQUAL OPPORTUNITIES

Ductal Calculi: The Laparoscopic Approach

15th-17th January 1997

Course Director Professor A Cuschieri

Course Tutors Mr S Shimi
Miss Peta Dunkley
Mr C Hensman

A 3 day laboratory based course designed for surgeons who have mastered laparoscopic cholecystectomy and wish to progress to single stage managements of ductal calculi at the time of laparoscopic cholecystectomy.

The course covers the management issue as well as essential endoscopic skills required such as cannulation of common bile duct, choledocoscopy and stone extraction. The emphasis is on relevent skills training using specially designed tissue simulations.

Live recorded video will be used to illustrate the application of these skills.

The practical course offers;

- experienced tutors
- small group tuition
- intensely practical programme
- 'hands on' practical sessions
- live theatre link (when possible)
- practical hints
- troubleshooting

Course fee excludes accommodation but includes all course materials.

SURGICAL SKILLS UNIT

Thoracoscopic Sympathectomy

3rd-5th February 1997

Course Director Professor A Cuschieri

Course Tutors Mr R Walker
Miss Peta Dunkley
Mr C Hensman

A 2 day lab based skills course concentrating on the techniques required for endoscopic sympathectomy. The course covers the anatomy of the autonomic nervous system, the wider indications for surgery, instrumentation, safe access and anaesthetic implications. Practical exercises highlight the various procedures which may be carried out such as ganglionectomy, ramisectomy and interganglionic neurotomy.

The practical course offers;

- experienced tutors
- small group tuition
- intensely practical programme
- 'hands on' practical sessions
- live theatre link (when possible)
- practical hints
- troubleshooting

Course fee excludes accommodation but includes all course materials.

APPLETON & LANGE
New Edition

The recognised standard for all general surgeons and surgeons in training

Maingot's Abdominal Operations, 10/e

Michael J. Zinner, MD, FACS,
Moseley Professor of Surgery, Harvard University Medical School, Surgeon-in-Chief, Brigham and Women's Hospital, Boston

The most current diagnostic procedures and techniques related to the management and care of abdominal surgical patients are presented in this new, two-volume set.

New Features

- more operative procedures, new concepts in diagnosis and new management of diseases
- new chapters on benign disorders of the oesophagus, surgical procedures to replace the oesophagus, continent ileostomies, surgical management of ascites, common bile duct exploration and gynaecologic pelvic procedures
- contemporary endoscopic and laproscopic techniques
- 80% new illustrations - over 700 brand new
- Gastrointestinal Syndromes sections updated

Pub. Mid December 1996 1,800 pages (approx.)

Dual Set (Vols I & II)	$295	£195	(08385 06275)
Vol I only	$175	£117	(08385 61047)
Vol II only	$175	£117	(08385 61055)

Crawford William Jamieson MS, FRCS

The British Journal of Surgery has been remarkably fortunate with its last three chairmen, who have moulded the Journal from a parochial news-sheet into an important international publication of renown. Each has placed his mark on the Journal, and each has provided a degree of stability to its affairs, such that the Journal is now wholly owned by the British Journal of Surgery Society (and therefore by British surgery). When Crawford Jamieson joined the organisation as Assistant Editor in 1977 the BJS was owned by John Wright, the Bristol publisher, in partnership with the BJS Society. That partnership had been formed by the first editor Ernest Hey Groves and John Wright, reputedly in a coffee shop in Bristol; no written record of the agreement existed. By wise and skilful negotiation, Leslie LeQuesne formalised the arrangement with a buy-out clause, largely orchestrated by the then Treasurer, Hugh Dudley. Preparations for the buy-out were set in hand for early in 1983 by which time Hugh Dudley had taken over as Chairman. The managing director of John Wright, aware of possible change, invited the editors to a pre-Christmas lunch. Well briefed by the Chairman, the editors held true to the line; the Editor, Crawford Jamieson, displaying his qualities of tact, diplomacy, suave urbanity and sound business sense, kept the conversation firmly in the field of play. Perhaps, Crawford displays his talents best at the dinner table, guiding conversation and directing business to a successful conclusion. Once John Wright had been set aside, the Journal was published by Butterworth and Co. until the next contract was ripe for negotiation. With skill, firmness and foresight, that contract was established with Blackwell Science Ltd by Crawford Jamieson in his capacity as Chairman. The Journal has benefited enormously from this agreement with BSL, as has British surgery through the British Journal of Surgery Society Ltd.

Crawford has guided the BJS as Chairman since 1988, having previously been Assistant Editor to Mr Felix Eastcott in 1977, and Editor from 1978 to 1987, years of growth and influence within the Journal. His experience as Editor enabled him to maintain an intimate knowledge of BJS affairs, yet leave the Editor to run the Journal. The arrangement within the BJS is that it is managed by the British Journal of Surgery Society, which deals with all the business affairs, including any profit that accrues from its publication. The Chairman chairs the meetings of the Council of the Society at which all business matters are discussed and any profits are distributed within British surgery. The Editorial Committee is also chaired by the Chairman, but at the meeting of this committee publishing, promotion and policy of the Journal are considered with the publishers. For instance, the discussion on the size of the Journal and the standing in the citation index are hotly debated, rigid views being tempered with an anecdote from the Chairman related to fish or fowl or surgery.

The skill of the Chairman lies in balance and decisiveness, talents that Crawford has shown throughout his long service. Like his predecessors he has given unstinting diligence, devotion and humour to the affairs of the BJS.

R. C. G. Russell
Chairman
British Journal of Surgery Society

Mr Christopher Russell, a former Editor of the Journal, has taken over from Mr Jamieson as Chairman of the Editorial Board since May 1996.

Technique of hepatectomy

In the past two decades hepatectomy has evolved from a rough, hasty and bloody procedure that could be performed only by a few experts to a refined, deliberate and relatively bloodless operation that can be carried out by many trained general surgeons. The operative mortality rate for cirrhotic patients has decreased from 58 per cent in Foster's survey in 1977 to less than 5 per cent in many recent series. The 5-year survival rate after hepatectomy for hepatocellular carcinoma (the most common indication for hepatectomy in the East) has also improved to about 50 per cent[1]. Although it may be argued that some improvement in survival is related to the lead-time bias associated with resecting small tumours in patients with good liver function, the major contributory factor to early success is improved surgical technique. Numerous technical innovations relating to hepatectomy have now been reported. They aim to increase the resectability rate by including nearby organs, major blood vessels or bile duct affected by the malignancy[2] and to allow surgery on high-risk patients, for example those with bile duct obstruction, intrahepatic recurrence or suboptimal hepatic function[3]. Such heroic approaches will benefit only a fortunate few, because the prognosis of patients with advanced malignancy and cirrhosis is usually dismal. Unless a substantial period of good quality of life is attained, the classical criteria for selection of patients for hepatectomy must hold, i.e. unilateral disease and sufficient liver function.

At present the technique of hepatectomy is fairly standardized but variation in special circumstances should be exercised to achieve the best results. Surgeons should aim at reducing blood loss, ensuring an adequate tumour-free resection margin and protecting the liver from hypoxic injury. Massive bleeding has been recognized as detrimental, but this can generally be avoided nowadays. However, avoidance of exogenous blood transfusion should be the ultimate aim because such transfusion adversely affects long-term survival[4]. An adequate tumour-free resection margin can be marked out accurately using intraoperative ultrasonography on the surface of the liver, but adequate resection can be achieved only if the ultrasonic dissector is applied carefully during liver transection. Unexpected liver function impairment may be due to inadvertent and prolonged application of a retractor over the hepatoduodenal ligament or rotation of the liver lobe[5], both of which should, therefore, be avoided.

Excellent exposure of the liver can generally be achieved using a bilateral subcostal incision and a self-retaining retractor. The right lobe can be mobilized and rotated to the wound surface if necessary. This manoeuvre is easy when there is a soft and normal liver, but it is potentially dangerous in the presence of a large cancer as the space for manipulation is limited. During exposure for segmentectomy of segment 7 or 8, prolonged rotation of the liver is undesirable because the inflow and outflow pedicles will be twisted[5]. In such difficult situations a thoracic extension to the subcostal wound or a J incision[6] should be favoured to allow the liver transection plane to be perpendicular to the wound.

Preliminary hilar dissection is necessary for division of the ipsilateral inflow vasculature for lobectomy. In the case of segmentectomy, it may be used for hemivascular control or the intrahepatic posterior approach[7]. Dissection of the right or left hepatic duct within the hilar plate is not desirable as it may damage the blood supply to the bile duct. Division of the hepatic duct is best left to the stage of parenchymal transection at the liver hilum, by which time the hepatic duct can be seen clearly and ligated with the tissue of the hilar plate.

Control of the right hepatic vein outwith the liver is difficult when dealing with a large tumour of the right lobe. Forceful mobilization of the liver will disseminate cancer cells or lacerate the right hepatic vein or inferior vena cava. Transection of the liver from its anterior surface down to the anterior surface of cava without prior mobilization (anterior approach) may be advantageous in this situation[8]. Such an approach can be accomplished only with an ultrasonic dissector, as it is difficult to transect liver tissue in front of the inferior vena cava using a crushing clamp or finger fracture technique. The ultrasonic dissector facilitates liver transection by allowing a clear exposure of the blood vessels, which permits a reduction in blood loss and a wider tumour-free resection margin[9]. However, its use is time consuming and may not be entirely bloodless, especially when a high power is set. Furthermore, it may be associated with spread of viral hepatitis. The ultrasonic dissector is, therefore, not the final answer for hepatectomy; better equipment design is still desirable.

The Pringle manoeuvre is regarded as an efficient method of reducing blood loss during liver transection, but up to now there has been no prospective randomized trial confirming its absolute safety and efficacy. It is worthy of note that hepatectomy is increasingly being performed without inflow occlusion[3]. Cirrhotic livers, in particular, are probably more vulnerable to ischaemic injury than normal livers and surgeons should acquire the skill of transecting the liver without a Pringle manoeuvre to avoid ischaemic damage in such a situation. It is questionable whether the Pringle manoeuvre is needed after control of the inflow pedicle to the tumour-bearing lobe, because most bleeding then comes from the hepatic vein. Attempts have been made to produce a completely dry field by total (inflow and outflow) vascular occlusion, with or without supracoeliac aortic clamping, but the amount of bleeding during and after liver transection was not encouraging[10]. The ability to transect the liver safely without inflow and outflow vascular occlusion is a prerequisite for harvesting a left lobe graft in living-related hepatic transplantation. Mastering the technique of the anterior approach using the ultrasonic dissector opens the possibility of harvesting a right lobe graft from a living relative for transplantation into an adult recipient.

Despite several major advances in the technique of hepatectomy in the past decade, only vigilant attention to technical detail, together with careful perioperative management, leads to success. There is virtually no room for error in this challenging field of surgical activity.

The venous perforator

Phlebology is plagued, more than most specialties, with eponymous nomenclature. So it is, for example, that we have the lower-limb operations of Linton, Rob and Cockett to deal with superficial to deep venous connections, named according to their locations for Dodd, Bassi, Boyd or Hunter.

It has long been observed that the skin changes of chronic venous insufficiency (lipodermatosclerosis) are associated with conspicuously enlarged and incompetent perforating veins, notably at the medial border of soleus in the lower calf. This group of perforators is sometimes referred to as Dodd's perforators. The surgical instinct has been to attack them, on the assumption that they are causally related to the skin changes. Surgical onslaughts have taken a variety of forms, the more radical of which are subfascial ligation, as described by Linton[1] and Rob[2], and extrafascial ligation popularized by Cockett[3]. These operations, through incisions which often extend most of the length of the calf, require prolonged postoperative rest and limb elevation; they incur substantial early healing problems and late scar breakdown. Although a few authors have claimed satisfactory long-term results, such procedures have tended to fall from favour in recent years. Perforator interruption, by whatever method, has never to our knowledge been evaluated by clinical trial.

Endoscopic subfascial surgery is a neat alternative that has attracted attention recently in several countries, although it has been well known in Germany for around a decade. It was developed by Hauer[4], popularized by Fischer[5], and utilized in large series by Jugenheimer[6] and Sachs *et al.*[7]. The technique is relatively simple and is performed along with saphenofemoral ligation, thigh stripping and multiple phlebectomy. Through a small incision in the upper calf, well clear of any lipodermatosclerosis or ulceration, an endoscope is introduced between the deep fascia and the underlying muscle. The instrument is then advanced down to intercept incompetent perforating veins, which may be clipped, treated with diathermy or simply cut. In this way a previously formidable operation has been transformed into a minimally invasive procedure that can even be performed on a day-case basis. The problem is that this is an operation without clear indications. The fact that varicose veins exist, with or without skin complications, and are connected to the deep veins by perforators does not necessarily mean that such perforators are incompetent or that they need to be intercepted. Indeed emerging evidence suggests that perforator surgery may have an extremely limited place.

Perforators in health convey blood predominantly in an inwards direction, filling the intramuscular veins during muscle-pump diastole. When the perforator valves become incompetent in chronic venous insufficiency, as Bjordal's elegant studies showed[8], there is a bidirectional flux through incompetent perforating veins with a predominantly outward flow, which renders the calf pump inefficient. However, by simultaneously measuring pressure in deep, superficial and perforator veins of patients with varicosities and incompetent perforators, Bjordal also showed that perforator incompetence contributed little to ambulatory venous hypertension: when retrograde flow in the main saphenous vein trunk was interrupted by proximal saphenous occlusion, venous pressure at the ankle became normal. These observations are supported by the clinical studies of Stacey *et al.*[9], which demonstrated that laboratory measurements of venous function do not return to normal as a result of perforator surgery. Åkesson *et al.*[10], by performing superficial saphenous surgery and perforator surgery as two separate procedures, showed an improvement in superficial reflux and venous hypertension after superficial vein surgery, but no additional improvement was noted when perforator surgery was added. A further spanner has recently been thrown into the works by Campbell and co-workers[11] who, by means of duplex ultrasound studies before and after conventional varicose vein surgery to the superficial system, without perforator surgery, have shown that 80 per cent of incompetent perforating veins regain competence after operation.

It is interesting too to note that Zukowski *et al.*[12] have described 35 per cent of their patients with chronic venous disease as having, on duplex ultrasonography, the combination of incompetent perforators plus incompetent valves in the deep veins from the popliteal vein downwards. The importance of incompetence of the popliteal vein 'gatekeeper segment' has been highlighted in other recent studies relating popliteal incompetence to impaired ulcer healing and poor prognosis after subfascial ligation[13].

So it seems clear that indiscriminate interception of incompetent perforators cannot be justified. The availability of duplex scanning and endoscopic subfascial techniques offers opportunities to put this component of venous surgery on a rational footing. Several further types of studies are required. First, there is a need to confirm the relationship between superficial and (especially) deep vein incompetence and haemodynamically significant incompetent perforating veins. Second, comparisons of diagnostic techniques for identifying perforators could be combined with validation of the accuracy with which endoscopic surgery can locate and interrupt them. Finally, clinical trials are needed to compare the outcome of perforator interception and perforator sparing, in defined patient groups. Evidence-based medicine has not so far been a strong feature of phlebological practice.

Review

Desmoids in familial adenomatous polyposis

S. K. CLARK and R. K. S. PHILLIPS

The Polyposis Registry, St Mark's Hospital, Northwick Park, Watford Road, Harrow, Middlesex HA1 3UJ, UK
Correspondence to: Mr R. K. S. Phillips

Clinical desmoid disease affects approximately 10 per cent of patients with familial adenomatous polyposis (FAP); the subclinical rate is unknown. Desmoids are probably neoplastic rather than regenerative in origin and may arise in association with germline or somatic mutations at or beyond codon 1444 of the *APC* gene. Intra-abdominal desmoids behave unpredictably but are an important cause of death in those with FAP. Signal intensity on magnetic resonance imaging reflects tumour cellularity, which in part determines progression, and this may help management. Surgical treatment of advanced desmoids is hazardous, but medical treatments have limited success. Chemotherapy with doxorubicin and dacarbazine is currently under evaluation.

Desmoid tumours are a heterogeneous group of benign fibrous masses, at times clinically aggressive and even life threatening. They are classified as fibromatoses, a group of pathologies[1] resulting from proliferation of well differentiated fibroblasts that infiltrate and show repeated local recurrence but are neither unequivocally malignant nor inflammatory. Other fibromatoses include palmar, plantar and penile fibromatosis, keloids and low-grade fibrosarcoma.

The nomenclature and classification of desmoids is complex and confusing. Terms including aggressive fibromatosis, mesenteric fibromatosis and fibrosis are used to refer to these lesions. Classifications used by different authors vary subtly, making comparison difficult. Desmoids occur in association with familial adenomatous polyposis (FAP) or sporadically, and may be subdivided by site into extra-abdominal, abdominal wall or intra-abdominal[2]. There are differences in behaviour between FAP-associated and sporadic desmoids. Unfortunately, the literature often mixes desmoids and other fibromatoses, and includes FAP-associated with sporadic desmoids, making no distinction between these, and sometimes failing even to mention FAP.

Epidemiology

Desmoids are rare, accounting for less than 0·1 per cent of all tumours[3,4], with an annual incidence of 2–4 per million[5]. About 2 per cent of desmoids are FAP associated and patients with FAP are at about 1000-fold increased risk of developing desmoids compared with the general population[6]. Incidences from 3·6[7] to 13[8] per cent have been reported by various polyposis registries; 10 per cent of patients with FAP attending the Cleveland Clinic are actually being treated for desmoid tumours[9]. Both sporadic and FAP-associated desmoids have a peak incidence between 28 and 31 years of age, the reported range being from 5 months to 80 years. Sporadic desmoids are significantly more common in women, with a female:male ratio ranging from 2:1 to 5:1, but in FAP any sex difference is less marked[6,8,10–12], non-existent[13,14] or even reversed[15,16].

Paper accepted 12 June 1996

Desmoid disease is an important cause of morbidity and mortality in FAP, life-table analysis of patients with intra-abdominal desmoids at St Mark's Hospital revealing an overall 10-year survival rate of 63 (95 per cent confidence interval 44–82) per cent (*Fig. 1*). Desmoid-associated mortality rate in FAP ranges from 10 to 50 per cent[11,16,18,19], with a mean interval from diagnosis to death of 4[20] to 6[21] years. In one large study[21], desmoid disease was the second commonest cause of death overall in patients with FAP (10·9 per cent), after colorectal carcinoma (58·2 per cent). In patients who had prophylactic colectomy, desmoid disease was the commonest cause of death (30·6 per cent), periampullary carcinoma being second (22·2 per cent), with desmoid-related death occurring significantly sooner after colectomy and at a significantly younger age than death from other causes. Other studies have confirmed desmoid disease as either the commonest[22,23] or second commonest[24,25] cause of death overall after colorectal cancer in patients with FAP, and either the commonest or second commonest[24,26] single cause of death after prophylactic colectomy. Desmoids can also contribute to death from other causes by making surgery for rectal or

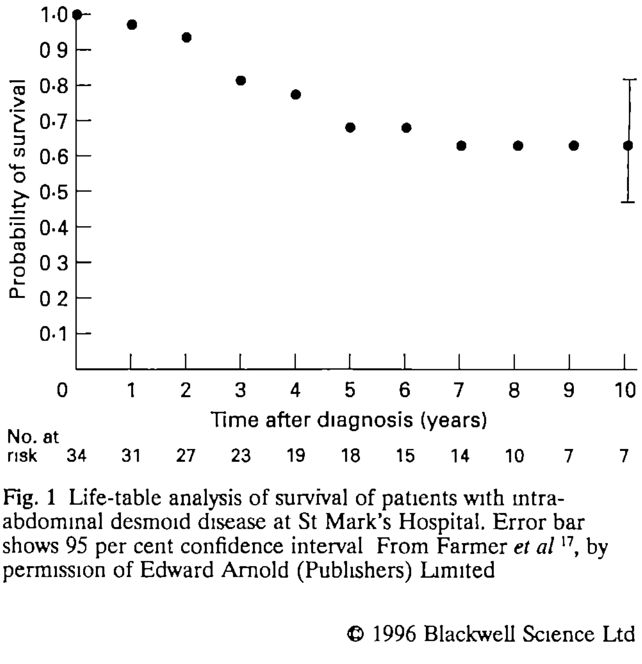

Fig. 1 Life-table analysis of survival of patients with intra-abdominal desmoid disease at St Mark's Hospital. Error bar shows 95 per cent confidence interval. From Farmer *et al* [17], by permission of Edward Arnold (Publishers) Limited

upper gastrointestinal malignancy difficult or even impossible[15,27].

Aetiology and genetics

Three factors, initiation by trauma, the influence of sex steroids and an underlying inherited defect, have been implicated in the aetiology of desmoids, although their precise role is unclear.

Trauma

Of intra-abdominal and abdominal wall desmoids in FAP, 68–86 per cent occur after abdominal surgery, the majority (55–75 per cent) within the first 5 years[6,8,11,15,16,28,29]. The average interval between surgery and the diagnosis of desmoid is 2–3 years, the reported range being 4 months to 28 years. The suggestion that the more extensive dissection in restorative proctocolectomy compared with ileorectal anastomosis might result in a higher incidence of subsequent desmoids is not borne out in the literature[15]. Despite the strong association with previous surgery, intra-abdominal desmoids can occur spontaneously in FAP[28], being found in 4 per cent of patients at the first laparotomy[15]. Only 30 per cent of sporadic abdominal wall desmoids occur after trauma[29] and these frequently arise in surgical scars[30]

Sex steroids

Oestrogens seem to stimulate the growth of sporadic desmoids in particular and abnormal oestrogen metabolism is also implicated in the pathogenesis of palmar fibromatosis, a related condition[31]. There is a higher incidence of desmoids in females, particularly those of reproductive age, and an apparent tendency for them to develop, especially in the abdominal wall, during or soon after pregnancy[3,4,32–34] or while taking combined oral contraceptives[14,31,35,36]. Any relationship between intra-abdominal desmoid and pregnancy has been questioned however[12,37]. The fastest growth rate is observed in young women[29], who also have the highest rate of recurrence of extra-abdominal desmoid after excision[38]. There have been reports of regression after the menopause[5,36,39] and after oophorectomy[40]. A case report has described an abdominal wall desmoid developing in a man treated with oestrogen for carcinoma of the prostate[41] which regressed after treatment was stopped. Desmoid-like lesions also occur in laboratory animals given oestrogens[42–44] and these can be suppressed with progestogens[42].

Oestrogen binding sites have been identified in 25–75 per cent[29,45,46] of mixed desmoids. Some desmoid cell cultures grow and produce collagen in response to oestrogen and are inhibited by the antioestrogen tamoxifen[47]. Recently, extra-abdominal desmoids have been found to express platelet-derived growth factor β, a potent mitogen for mesenchymal cells not normally produced by fibroblasts. This expression was increased by oestrogens[48].

Genetics

Sporadic desmoids do not seem to have a familial tendency, but Reitamo[49] found another abnormality of connective tissue (e.g. dental abnormalities, exostoses, incomplete spinal segmentation) on radiography in 80 per cent of patients with sporadic desmoid, compared with 7 per cent of normal controls, suggesting a basic functional inherited defect in connective tissue formation. Some familial clustering of desmoids in patients with FAP has been noted[8,10,20,32,50–53] and an increased risk of developing desmoids in first-degree relatives has been identified[6].

FAP, an autosomal dominant condition, can be considered to be a generalized disorder of tissue growth regulation caused by germline mutation in one copy of the *APC* gene. The *APC* gene has been localized to chromosome 5q22[54,55], cloned and sequenced[56–58], and mutations have been identified. It is estimated that about 10 per cent of cases of FAP arise as a result of a new mutation[59]. *APC* is a large gene consisting of 15 exons; exons 1–14 are small and exon 15 contributes 77 per cent of the coding region (codons 653–2843). The APC protein product localizes to the cytoplasm in epithelial cells[60] Although its precise function is not known, this protein associates with α and β catenins, which bind to cell-surface E cadherin and contribute to its role in cell adhesion and interaction[61,62]. APC protein is also thought to be important in formation of microtubules[63,64], which anchor the cytoskeleton and play a part in cell division. Most *APC* mutations occur between codons 900 and 1600, and almost always give rise to premature stop codons, resulting in a truncated protein product.

There is evidence of genotype–phenotype correlation in FAP: mutation at codon 1309 and large numbers of colonic polyps[65]; mutation at codons 1250–1464 and earlier death from colorectal cancer[66]; mutation 5′ of codon 160 and attenuated colonic polyposis[67]; mutation 3′ to a boundary in exon 9 and congenital hypertrophy of the retinal pigment epithelium[68]. Desmoids have been reported to occur more frequently in patients with mutation 3′ to codon 1444[69,70].

Wild-type APC protein is believed to form active oligomers, interaction between normal and mutant APC perhaps blocking function[71] to an extent related to the structure of the truncated protein. Proximal (5′) mutations result in severely truncated protein that may fail to oligomerize with the wild-type product of the remaining normal gene and thus have little effect on its function. More distal (3′) mutations result in a less truncated protein, which could interact significantly thereby impairing function. This ‘dominant negative’ effect may be further complicated by varying stability of the truncated APC protein in different tissues and subnormal levels of wild-type protein produced by the single remaining normal *APC* gene[66,72].

Identical mutations may be associated with diverse phenotypes[56,73], so genetic modifiers are probably involved in determining phenotype, as in the Min mouse[74]. Environment also influences phenotype, evidenced by polyp regression after colectomy[75].

Fibroblasts cultured from skin biopsies from patients with FAP[76–78] show similar defects in organization of cytoplasmic actin to those of tumour fibroblasts[79], abnormalities of growth pattern, and increased susceptibility to viral transformation, supporting the view that desmoid tumours are a phenotypic variant of FAP due to an abnormal fibroblastic response caused by the effects of the germline mutation.

An important step in the adenoma–carcinoma sequence is a somatic mutation (‘second hit’) in the remaining normal *APC* gene in the colonic epithelium[80,81]. A clonal deletion of 5q bearing the normal copy of *APC* has been identified in an intra-abdominal desmoid in FAP[82]. Loss of heterozygosity in 5q21–22, indicating loss of wild-type *APC*, has also been demonstrated[83,84]. Bridge *et al.*[85] described frequent clonal chromosomal rearrangements, especially 5q deletion, in fibroblasts from sporadic and FAP-associated desmoids. Almost all reported somatic mutations in desmoid tumours are deletions in exon 15[86,87] and lead to a downstream premature stop codon. Other abnormalities identified in sporadic desmoids include loss of chromosome 4[85] and trisomy 8[88,89], both of which have also been described in palmar and penile fibromatosis, and multiple complex chromosomal abnormalities[90]. There is thus some evidence that desmoids may result from a 'second hit' mutation followed by clonal expansion and therefore are true neoplasms.

A recent study[86] suggested that one of the two *APC* mutations in desmoids occurs at or beyond codon 1444, producing APC protein product of at least a certain length. This is irrespective of whether the mutation was inherited in the germline and is, therefore, present in all cells of the body, or was the result of a somatic mutation and clonal expansion.

Pathology

Desmoid tumour pathogenesis is not clearly understood. Desmoids may occur in any musculoaponeurotic structure, but the distribution varies markedly between those occurring in FAP, of which about 70 per cent are intra-abdominal, 15 per cent in the abdominal wall and 15 per cent extra-abdominal[6,11,14,28], and others where the abdominal wall (about 50 per cent) and extra-abdominal sites (40 per cent) predominate and only a minority are intra-abdominal (10 per cent)[91,92]. About 80 per cent of intra-abdominal desmoids are in the small bowel mesentery. Other sites documented include the transverse mesocolon, ligamentum teres and retroperitoneum[93]. In 5–38 per cent of cases multiple sites are involved[6,14,92,94]. Intra-abdominal desmoids most often give rise to life-threatening complications and are most difficult to treat, which explains why desmoids pose such a problem in FAP.

Mesenteric desmoids probably arise as flat white plaques and strands which contract, tethering the bowel and causing thickening and puckering of the mesentery. Further progression results in a discrete lobulated mass[8,95] (*Fig. 2*). There is no true capsule and the desmoid grows, compressing and infiltrating surrounding tissues such that the infiltrative margin may extend several centimetres beyond the palpable tumour edge. Eventually small bowel, ureters and mesenteric blood vessels may become encased and obstructed. Desmoids range in size from a nodule a few millimetres in diameter to a large mass. The cut surface is usually pinkish-white, often whorled, and may show evidence of cystic degeneration or haemorrhage, especially in large tumours.

Desmoids usually grow slowly but the rate varies during the course of the disease and they may behave somewhat more aggressively when associated with FAP[96]. Church[95] has suggested that 10 per cent of intra-abdominal desmoids in FAP disappear spontaneously, 29 per cent undergo cycles of growth and resolution, 47 per cent remain stable after diagnosis and 10 per cent grow rapidly. They do not metastasize and the only reliable report of malignant change occurred after radiotherapy[97]. Spontaneous regression has been documented in 4–17 per cent[11,49,98].

Histologically, desmoids consist of mature, highly differentiated fibroblasts in an abundant collagen matrix[99] (*Fig. 3*). Aggregates of lymphocytes are frequently located at the margins. There is a wide range of cellularity, often with acellular areas towards the centre of the tumour and a densely cellular periphery which can be mistaken for fibrosarcoma. Many of these cells are myofibroblasts[100,101], which are also found in repair tissue and malignant tumour stroma[102]. The cells have ill defined cytoplasm and pale nuclei. Mitoses are rare and nuclear atypia is absent. Electron microscopy has shown extensive intracellular collagen fibrillogenesis in the Golgi complexes of desmoid cells. This process usually occurs outside cells where collagen is formed from precursors secreted by the cells[103,104].

Presentation and complications

Desmoids are often asymptomatic and an incidental finding on examination or at laparotomy. They can be

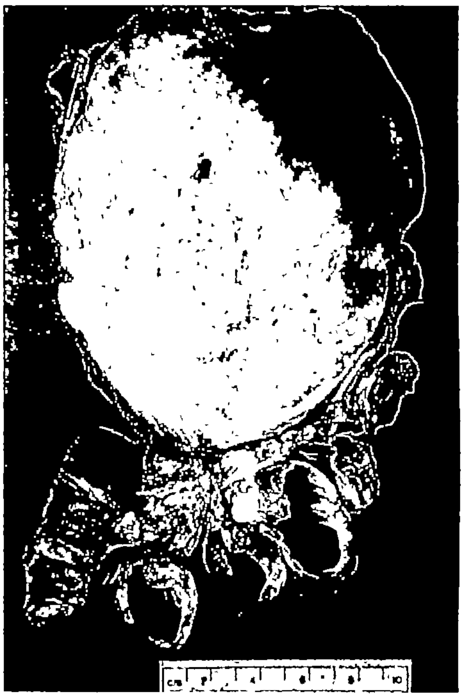

Fig. 2 Operative specimen of a desmoid arising within the small bowel mesentery

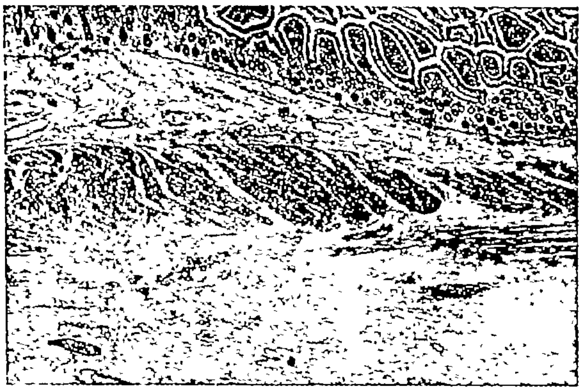

Fig. 3 Desmoid infiltrating the muscle of the small bowel (Masson trichrome, original magnification ×100)

very large before causing symptoms and may present simply as a mass. About one-third of intra-abdominal desmoids cause pain. Tethering and compression of the small bowel can cause obstruction, so progressive cachexia is a frequent problem. The mesenteric blood vessels may become occluded causing small bowel ischaemia[31], and central necrosis sometimes occurs within the desmoid. Fistula and sepsis may supervene[105,106] and are important causes of mortality.

Compression of large veins results in deep venous thrombosis; nerve compression can cause pain and sensory and motor deficits. Ureteric obstruction is common and respiratory failure[31], upper gastrointestinal bleeding[107] and aortic rupture[21] have been reported. Penna *et al.*[15] reported that 27 per cent of intra-abdominal desmoids cause hydronephrosis, perforation, impaired pouch function or obstruction requiring laparotomy. Desmoids found at laparotomy may interfere with planned surgery, preventing restorative surgery[108] or even resection of malignancy[109]. Some patients with FAP present with a desmoid before the colonic polyposis is detected[8,14,110], making investigation of the large bowel essential when an apparently sporadic desmoid is diagnosed.

Investigation

Laparoscopy caused bowel perforation in one study of chemotherapy for intra-abdominal desmoids[111] and cannot be recommended. Biopsy anecdotally has been implicated in accelerating tumour growth, but desmoid progression is notoriously variable and series in which several were biopsied do not support this[8]. Fine-needle aspiration cytology may be used, but histological confirmation is recommended, particularly to differentiate desmoid from low-grade fibrosarcoma[112,113].

Desmoids do not calcify, appearing on plain radiographs as a soft tissue mass displacing bowel loops. Intravenous urography and barium studies have been superseded by contrast-enhanced computed tomography (CT), which images the desmoid itself, although the former have some limited use in follow-up after surgery for bowel or ureteric obstruction. Angiography outlines neighbouring major blood vessels while also showing the usually sparse tumour vasculature, which contrasts with the extensive neovascularization of poorly differentiated sarcomas[114], but this investigation has also been largely replaced by enhanced CT.

Ultrasonographic scanning to investigate abdominal wall[115] and intra-abdominal desmoids[116,117] can localize a mass, but CT is required to demonstrate soft tissue density. Mesenteric desmoids appear as well demarcated solid masses with varying degrees of echogenicity due to mesenteric fat, blood vessels and cystic degeneration, but changes are not specific and cannot be used to distinguish a desmoid from mesenteric lymphadenopathy, lipoma or sarcoma.

Several radionuclides are taken up by desmoids. [^{99m}Tc(V)]dimercaptosuccinic acid is taken up more reliably than gallium-67 citrate and has the advantage that scanning can be done hours rather than days after injection[118]. This type of imaging may be useful in follow-up after treatment as it has greater sensitivity than CT in the differentiation of residual scarring from active disease[119,120].

CT is now the best choice for investigating intra-abdominal desmoids; the appearances have been well described[94,116,121–123]. Early mesenteric lesions appear as ill defined soft tissue infiltration of mesenteric fat (*Fig. 4*). Later, a mass (as small as 2–3 cm) may be seen, with displacement, infiltration (with the appearance of 'whiskers' extending into the mesenteric fat), tethering and encasement of small bowel loops. Desmoids show mixed attenuation and variable enhancement. Computed tomographic appearances correlate poorly with symptoms in intra-abdominal desmoids, but tumour diameter greater than 10 cm, multiple mesenteric tumours, bilateral hydronephrosis and extensive small bowel involvement are poor prognostic markers[123]. Abdominal CT may show regression of bulky tumours, but small bowel matting and adhesions following colectomy may be difficult to distinguish from residual or recurrent desmoid[111].

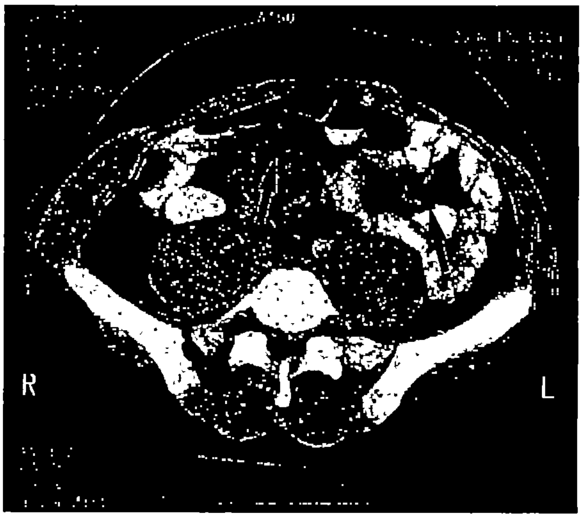

Fig. 4 Computed tomogram showing early desmoid in the small bowel mesentery

Magnetic resonance imaging (MRI) has advantages when investigating extra-abdominal desmoids[124–127]. Not only does it have multiplanar imaging capabilities, but contrast resolution is superior to that of CT, particularly in the presence of postoperative or radiotherapy changes[127]. The MRI features of both extra-abdominal[128,129] and abdominal wall[130] desmoids have been documented. The image intensities are heterogeneous, but overall there is low or similar signal intensity relative to muscle on T_1-weighted images and variable signal intensity on T_2-weighted images. There is good delineation of vascular involvement and variable enhancement with gadolinium–diethylenetriamine penta-acetate[131]. T_2-weighted sequences correlate best with histological findings[129,132,133]; high signal intensity is associated with increased cellularity, and low intensity is due to parallel orientation of abundant collagen and decreased density of mobile proteins in relatively acellular areas. Perhaps active cellular areas within desmoids might be detected by means of T_2-weighted sequences, thereby aiding prediction of tumour growth.

Treatment

Treatment is controversial, empirical and difficult. It is based largely on anecdotal reports and small, poorly controlled studies of predominantly sporadic desmoids, most of which are retrospective, encompassing long time spans, changing techniques and varying in follow-up. Many lack detailed information on desmoid site or FAP status.

Surgery

Surgery is widely accepted as the first-line treatment for extra-abdominal and abdominal wall desmoids, despite recurrence being common (20–80 per cent)[2,11,18,34,49,134]. The infiltrative nature of the lesion makes completeness of excision difficult to judge clinically, but there is controversy over the importance of excision margins. Some series[19] show a higher recurrence rate after incomplete or marginal excision compared with wide excision, but even without wide excision there may be no recurrence. Abdominal wall reconstruction with polypropylene mesh, polytetrafluoroethylene sheet or a myocutaneous flap may be required[135–137].

Mesenteric desmoids are rarely small enough or sufficiently localized to allow complete excision, and the most frequent site at the root of the small bowel mesentery and intimate relation to the mesenteric vessels means that often a considerable length of small bowel has to be sacrificed[93] when resection is possible. This surgery is hazardous, with a perioperative mortality rate of 10–60 per cent, usually from blood loss[11,12,17,37,138], and a major morbidity rate of 22–60 per cent. Recurrence here is more frequent than at other sites[8,11,20], occurring in 65–88 per cent. Sporadic desmoids and those associated with FAP behave differently, the latter having a higher recurrence rate even if excised completely[33,96]. Partial excision (but not biopsy) may accelerate growth[8]. There have been two reported cases of small bowel transplantation following enterectomy to excise large mesenteric desmoids[139,140]. Most authors[8,95] recommend that surgery should be avoided for mesenteric desmoids because of the risk of accelerated growth and high risk of recurrence. Nevertheless, operation may be needed to bypass bowel obstruction or relieve ureteric obstruction, either with stents or by ureteroureterostomy[17].

Radiotherapy

Radiotherapy by various techniques has been used; a total dose of 50–60 Gy by external-beam interoperative treatment[141] or brachytherapy[142,143] have yielded similar results. Radiotherapy was used primarily to avoid mutilating surgery, but more recently it has been employed as an adjunct to surgery when excision is incomplete or when recurrent disease has been resected. There is evidence that this may reduce recurrence rates both at extra-abdominal sites[19,134,144–147] and in the abdominal wall[148,149]. Recurrence rates of 40–70 per cent after surgery alone are reported to drop to 20–40 per cent when radiotherapy is added, leading some authors[38,144] to recommend its routine use when anything less than a wide excision is performed. Treatment with radiotherapy alone has been associated with local control rates similar to those after surgery alone[147], but tumour regression can be slow.

Intra-abdominal desmoids treated by radiotherapy behave differently, either not responding[11,37,150], or increasing in size[9], or showing a higher recurrence rate after adjuvant radiotherapy than after surgery alone[49] Furthermore, the use of radiotherapy at this site is limited by radiosensitivity of surrounding intra-abdominal structures. Nevertheless, a handful of patients have been treated with some success[134,142,151–153]. Intra-abdominal desmoids may be less radiosensitive than those at other sites and any effect of radiotherapy may possibly be a byproduct of ovarian irradiation[3], explaining the better results in women than men in some reports[14,32].

Pharmacological treatment

Various medical treatments have been reported to give mixed success. Non-steroidal anti-inflammatory drugs (NSAIDs) and antioestrogens are the most frequently employed and most widely documented, but other modifiers of adenosine 3′,5′-cyclic monophosphate (cAMP) metabolism, corticosteroids, colchicine, interferon α, interleukin 2 and warfarin have all been used. There have been reports of desmoid regression, sometimes dramatic, associated with some of these, but none is predictably efficacious and there are almost as many reports of failure as of success. There have been no prospective randomized trials and it is difficult to assess the value of different drugs because of the small numbers in each study. Again sporadic and FAP-associated desmoids, and tumours at different sites, are often reported together. This, coupled with the fact that drugs are often used in combination, can make the interpretation of results difficult.

Sulindac and indomethacin are the NSAIDs that have been used. They inhibit prostaglandin synthesis, which is thought to promote immunological attack on tumour cells, and also inhibit ornithine decarboxylase, an enzyme associated with tumour proliferation. In addition, they are known to cause a decrease in cAMP concentrations in tumour cells, which can lead to interruption of the cell cycle. There is evidence that NSAIDs can reduce tumour growth in experimental models[154] and polyp numbers in the rectal stump of patients with FAP following ileorectal anastomosis. Overall, the studies of NSAIDs alone[98,155,156] show an objective response rate of about 50 per cent (*Table 1*). There are also reports of their use in combination with antioestrogen[8,98,155,156] or ascorbic acid[157]. Most responses occurred at from 2 weeks to 3 months of treatment, but some were observed up to 2 years after the start of therapy. In a retrospective controlled study Tsukada *et al.*[98] showed significant benefit from tamoxifen, sulindac or indomethacin, alone or in combination, compared with controls not given any drug treatment, and of sulindac alone compared with these other drugs. There is evidence that sulindac, in particular, can be effective and, as NSAIDs are relatively non-toxic, it is often used as a first-line treatment.

Antioestrogens were used in logical response to the observations of the influence of sex hormones on desmoid growth. Some success has been achieved with progestogens, such as medroxyprogesterone acetate[158], and goserelin has also been used[159]. Testosterone use has shown no benefit[99]. Most attention has focused on the triphenylethylene, tamoxifen[32], and its chlorinated analogue, toremifene.

Oestrogen receptor blockade restricts RNA synthesis and alters the transcription of genes involved in tumour growth. However, not all desmoids are oestrogen receptor positive and, as is the case in carcinoma of the breast, alternative mechanisms of action have been suggested. Tamoxifen has an effect on prostaglandin metabolism and may also act via stromal–epithelial interactions[160], inducing transforming growth factor β production in stromal fibroblasts, which inhibits fibroblast growth *in*

vitro[161]. Antioestrogen binding sites distinct from oestrogen receptors have been identified in 79 per cent of desmoids[45].

Most patients treated with tamoxifen or toremifene have been women, who were often given NSAIDs or other treatments in addition[32,35,51,156,162–164]. Taken together, the studies (*Table 2*) show an objective response rate of about 50 per cent when treating intra-abdominal desmoids in FAP with antioestrogens alone[51,155]. Response can be variable, even between different tumours in the same patient, and the initial response occurs between 2 weeks and 6 months after the start of treatment.

Theophylline, testolactone and chlorothiazide synergize the action of adenosine 3′,5′-monophosphate and may inhibit adenosine 3′,5′-monophosphate diesterase[31]. This causes a rise in intracellular cAMP levels and has been shown to differentiate Chinese hamster ovary cells to mature fibroblasts *in vitro*. There have been a few reports of the use of these drugs to treat desmoids, with mixed results[8,31,33,165]. Ascorbic acid, which causes a fall in intracellular cAMP concentration, has also been used in a few patients, particularly in combination with NSAIDs[157]. Again, the results are mixed and on the whole unconvincing.

Glucocorticoids inhibit growth of desmoid fibroblasts in culture[166] and have been effective clinically in a few cases[167,168]. Colchicine disrupts microtubules, causing a decrease in intracellular collagen formation. It is used in the management of palmar and penile fibromatosis and there is a single report of its use in sporadic extra-abdominal desmoid disease, with good result[169]. Warfarin[155] and interleukin 2[170] have been tried with little benefit, but a single case report[171] of treatment with interferon α, which inhibits fibroblasts and stimulates collagenase *in vitro* and is used to treat keloids and systemic sclerosis, was promising.

Cytotoxic chemotherapy

Cytotoxic chemotherapy was originally used as a last resort in recurrent, irresectable or aggressive desmoid disease because of the similarities between this and low-grade fibrosarcoma. In general, objective remissions of variable degree and duration have been noted with almost all agents, including actinomycin D, cyclophosphamide and vincristine[172], actinomycin D, vinblastine and methotrexate[173,174] and others[9,52,144], but the numbers reported are small.

There is increasing evidence that the antisarcoma regimen consisting of doxorubicin and dacarbazine is effective in the treatment of life-threatening intra-abdominal desmoid disease in FAP. Nine cases have been reported (*Table 3*)[111,175,176], with complete tumour regression in four and partial regression in five. In another case doxorubicin was used alone, with subsequent partial tumour regression[170]. These results have prompted the authors of the most recent report to recommend that this treatment should be considered for patients with FAP with symptomatic irresectable desmoid that is unresponsive to conventional medical therapy, and to suggest that it be used at an earlier stage in the management of such patients.

Treatment recommendations

Desmoids are pathologically benign, have a variable growth rate, and occasional examples of spontaneous regression have occurred. Surgery carries considerable risks in intra-abdominal disease and there is a lack of consistently effective alternatives. There is, however, substantial mortality and morbidity associated with desmoid tumours. Despite the fact that doxorubicin and dacarbazine are potentially toxic, they should be considered in some cases of clinically aggressive disease.

The treatment protocol developed at St Mark's Hospital after a comprehensive review of the literature recommends imaging by CT and initial treatment with sulindac 150 mg twice daily for 6 months. If growth continues, toremifene 180 mg daily is added. If the desmoid is still growing or is giving rise to significant symptoms after a further 6 months, MRI is performed to assess tumour cellularity, and doxorubicin and

dacarbazine chemotherapy considered. Any patient presenting with a rapidly growing or severely symptomatic desmoid is started on both sulindac and toremifene at the above doses, and cytotoxic chemotherapy is considered immediately. Once a desmoid has stabilized or regressed, the doses of sulindac or toremifene can be reduced cautiously. If a desmoid is found at surgery that can be resected with a minimum of small bowel, this should be done. Otherwise, surgery is reserved for obstructive complications and abdominal wall desmoids.

Conclusions

Desmoid tumours, particularly when intra-abdominal, are a serious and increasing problem in patients with FAP. It is not known whether they are, indeed, true neoplasms or the result of a generalized fibroblast abnormality; there is increasing evidence to support the former. Further study of the underlying genetics and molecular biology of desmoids may allow the identification of patients who are at particular risk of their development. This raises the prospect of modifying the management of this group, perhaps delaying colectomy slightly, employing minimally invasive techniques to reduce surgical trauma or opting for primary restorative proctocolectomy to avoid subsequent surgery. Recognition of high-risk patients may justify clinical trials of perioperative prophylaxis.

It has been proposed that the incidence of intra-abdominal desmoids may have been underestimated, as some never progress to become symptomatic[8]. It is known that desmoids are more likely to recur after surgery if large[2], and it has been suggested that treatment may be more effective when the tumour burden is small[156]. More intensive screening of those with FAP for intra-abdominal desmoid disease would establish the true incidence, improve knowledge of the natural history and allow early treatment. Although desmoid disease can run a severe course, prolonged periods of stability and even regression have been reported. There is a need to identify the minority of desmoids that grow rapidly, so that they can be treated aggressively. MRI may offer some prognostic information and may also be valuable in monitoring response to treatment. Finally, further studies of the treatment of intra-abdominal desmoids in patients with FAP are required to establish optimal protocols. These studies will probably need to involve several centres in order to overcome the problems caused by the rarity of this condition.

Review

Abdominal wounds in war

R. COUPLAND

Medical Division, The International Committee of the Red Cross, 19 Avenue de la Paix, CH 1202 Geneva, Switzerland
Correspondence to: Mr R. Coupland

The reported mortality rate associated with abdominal wounds sustained in war varies considerably because of the heterogeneity of wounds and the different circumstances under which figures have been collected rather than different treatment strategies. This review draws together a personal experience, reports from ten wars, and information from a database for war wounded into an analysis of abdominal wounds. The analysis attempts to bring understanding to why people die with abdominal wounds in war and so clarifies logistic and treatment issues.

Abdominal wounds caused by missiles during armed conflict are common and life threatening. They are the wounds for which surgery has the greatest impact on overall survival[1]. They carry a potentially high mortality rate if not treated or if treated incorrectly, and a normal life is possible for the majority of survivors. The factors that determine mortality from abdominal wounds in war are complex and difficult to quantify. Reported figures vary considerably; one reason is that they have been collected under different circumstances. The arrival of many casualties, delay before reaching a surgical facility and lack of surgical resource or expertise are factors that increase mortality; only tangential reference is made to them. There is no universally accepted quantification of injury severity. The result is that operative strategies, especially colostomy, have assumed great importance.

My experience with abdominal war wounds has been gained in nine countries in the Middle East, Africa and Asia where hospitals have been established by the International Committee of the Red Cross (ICRC) to treat the war wounded. In these hospitals, general surgeons work with a basic level of technology (by policy) and without onward referral to specialized colleagues. The wounded tend to arrive within 24 h of injury but only about one-quarter arrive within 6 h; approximately 10 per cent require laparotomy[2,3]. The majority with abdominal wounds arrive in a good general condition with a systolic blood pressure of over 100 mmHg. At laparotomy there is always some blood in the abdominal cavity but active bleeding is found rarely, even from hepatic wounds. Life is usually threatened by intestinal perforations alone and in such situations there is a good chance of survival (*Fig. 1*). However, armed banditry and changes in political or military circumstances may mean that the wounded arrive at hospital within minutes of injury and in such cases another form of abdominal trauma is seen. Casualties may have large abdominal wounds, often with evisceration, active bleeding and multiple organ injury (*Fig. 2*); they arrive hypovolaemic and in poor general condition. Nevertheless, they are a minority of those with abdominal wounds. Close-range shotgun wounds are the civilian equivalent[4]. In my hands, in the context of an ICRC hospital and despite urgent operation, most people with these severe abdominal injuries die on the operating table or shortly after surgery. Haemorrhage may be controlled but repair of the associated intestinal, hepatic or vascular wounds may not be possible. There may be more than one missile track and there are frequently wounds in other regions. Successful treatment of severe abdominal wounds

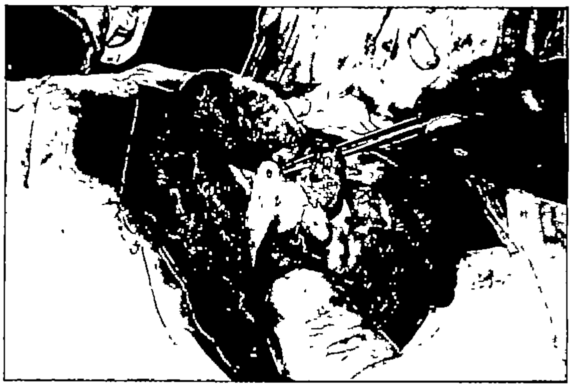

Fig. 1 Laparotomy in a patient wounded by a hand grenade more than 24 h previously. The only visceral wound was perforation of the small intestine by a metallic fragment (shown) Fibrinous exudate is visible on the other loops of intestine. The perforations were sutured and recovery was uneventful

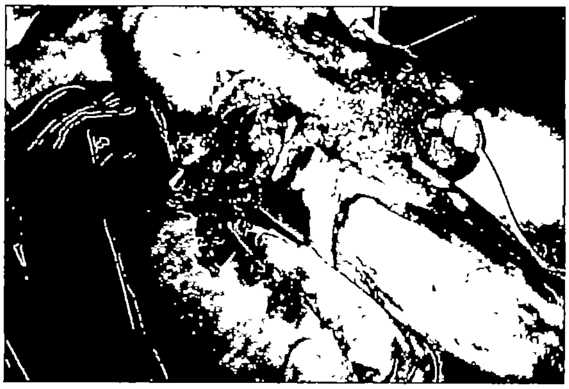

Fig. 2 Missile wound of the abdomen. The patient's general condition was poor on admission, with a systolic blood pressure of 70 mmHg. Apart from evisceration, he had multiple perforations of the small and large intestines with iliac vessel injury. Despite urgent surgery he died on the operating table. One factor contributing to death was limited blood for transfusion

---

Paper accepted 27 June 1996

requires urgency, a high level of surgical expertise, technological resource and, importantly, an adequate supply of blood for transfusions[5]. Provision of these may be impossible when the fighting is close to the hospital.

Outside the basic but organized facilities in an ICRC hospital, I have witnessed civilian hospitals that were so disrupted by the conflict that the wounded arrived in the operating theatre without assessment, resuscitation or documentation. Anaesthesia was given by an unqualified anaesthetist and those doing the operations were challenged by the most straightforward of procedures. Postoperative care was the responsibility of the friends or relatives of the wounded person. All intravenous fluids, antibiotics, analgesics and their administration had to be bought; they were given for the first time 2 or 3 days after admission, assuming they had been prescribed in the first place. In one such situation, an ICRC medical team was fully occupied in finding and treating unresuscitated people who were about to be operated on or who had recently had operations. The mortality rate from laparotomy before the intervention of our team was certainly near to 100 per cent whether or not there was intra-abdominal injury. With non-operative management at least 20 per cent could have survived[1,6,7].

In some countries, senior military surgeons have the attitude that front-line surgery is good experience for 'the young surgeons'. In one such country, a 'young surgeon' informed me that the situation at the front-line hospital was dangerous and chaotic. He and his colleagues were expected to operate on all casualties and so they were opening the abdomen of soldiers with abdominal wounds on the slightest pretence, under ketamine anaesthesia, and after a minimal intervention simply closing them again. They hoped more competent care would be reached later. Criticism by their seniors and other soldiers for not working was thus avoided. When duty surgeon in the ICRC hospitals, I have admitted many people who have had a front-line laparotomy. They usually arrive dehydrated with pus, faeces, urine or bile leaking from wounds, incisions or drain sites (*Fig. 3*); there is rarely any clinical record. After rehydration, antibiotics and correction of anaemia, a second laparotomy reveals missed perforations, leaking anastomoses or repairs, and retained surgical compresses. The associated mortality rate is so high that it is difficult to know whether a second operation has any benefit over conservative management. The fact that both the extent of injury and the operation performed are unknown makes this a difficult clinical decision for the receiving surgeon. I am sure that these patients would have fared better with front-line resuscitation only and immediate transfer to the ICRC hospital.

Although critical of this surgical practice, I should point out that I have been placed in situations where fatigue, fear for my own safety and disruption of the organized hospital infrastructure by the conflict may have rendered my own practice unsafe and unsound. This is the reality of war. It underlines the importance of correct first aid and transportation of the wounded to an organized, competent and reasonably secure surgical facility. In the light of such experience, this paper reviews data from World War II, nine more recent conflicts, urban bullet wounds from South Africa and the USA, and figures from the wound database of the ICRC. It is an attempt to quantify the factors influencing mortality from abdominal wounds, taking account also of the impact of the constraints that arrive with war.

Fig. 3 Admission photograph of a patient who had had a field laparotomy 48 h previously. There was no accompanying information. His general condition was poor; pulse rate was 120 per min and systolic blood pressure was 100 mmHg. The fluid draining from the small tube drain smelled of faeces, the bullet entry wound on the left side of the abdomen had been sutured It was decided further laparotomy was indicated. A sutured perforation of the small intestine and open perforation of the rectosigmoid junction were found and a colostomy was performed. The abdomen was closed with difficulty because of necrotic tissue in the previous surgical wound The patient died 24 h after operation

Review of the literature

The reported mortality rate from abdominal wounds in recent wars or civilian series of gunshot wounds is shown in *Table 1*[2,3,8–21] and for treated patients varies between 3 and 31·4 per cent; there is no uniformity of data collection. Figures may relate to all abdominal casualties[13,20], only those who reach hospital alive[3,12,15], those who have a wound of the abdominal region[12,20] or only those who have a laparotomy[2,3,8–21]. Some reports are small series[2,3,8,11,14]. In addition, the multiplicity of wounds may mean the eventual outcome for a patient is unrelated to his or her abdominal wound or its treatment[12,13,20]. Mortality may increase with a particular cause of injury, for example bomb blast[13]. A long evacuation time may alter in-hospital mortality[1,8,18]. In a triage situation, only those wounded whose lives are salvageable by laparotomy may be registered[14–16,20]. Alternatively, deaths may be registered only in the early phase because of onward evacuation of the wounded to other facilities[12,16].

Some references acknowledge the heterogeneity of abdominal wounds and the implication for mortality. Rozin and Kleinman[15] judged that 21 per cent of people required operation before evacuation to a base hospital because of severe abdominal injury, as indicated by hypovolaemia and large abdominal wounds; the eventual mortality rate was 18·9 per cent. Other reports associate a high mortality rate with hypovolaemia on admission[19,22]. Whatever the organ injured, if it is injured in isolation there is a lower mortality rate; understandably, the rate rises with the number of organs injured[2,8,9,12,18–20,22]. This is better documented and quantified in civilian gunshot series[6,7,17]. Where the main cause of injury was handgun bullets, Feliciano *et al.*[17] found that 25 per cent of abdominal gunshot wounds affected major abdominal vessels and carried a mortality rate of 39·2 per cent, while Collins *et al.*[23] reported a rate for such injury of 22·2 per cent. In war, these injuries are reported to carry a mortality rate near to 100 per cent[2,10,13]; however, some authors have not referred to this as part of laparotomy

Table 1 Mortality from abdominal wounds and/or laparotomy from wars

Reference	Year	Conflict or country	Total no. of casualties	No in series	Mortality rate (%)	Comment
Ogilvie[8]	1944	World War II	—	628	39·2	Forward surgery but follow-up deaths recorded
Imes[9]	1945	World War II	—	358	20·1	Penicillin available Possibly first reported series
Jones *et al*[10]	1968	Vietnam	1011	158	—	158 laparotomies Improved mortality claimed No figures given
Xeros and Symeonides[11]	1976	Cyprus	—	80	14	General hospital care
Hardaway[12]	1978	Vietnam	17726	1350	4·5	(i) 2454 'abdominal wounds' but only 1350 laparotomies. (ii) Deaths recorded only before evacuation from Vietnam
Owen-Smith[13]	1981	Northern Ireland	2000	267	41·2	All abdominal wounded including those dead on arrival at hospital
				51	31	Mortality after laparotomy (values include 33 per cent bomb blast)
Jackson *et al.*[14]	1983	Falkland	233	30	3	Mortality from laparotomy Forward surgical team
Trouwburst *et al*[3]	1987	Afghanistan	1033	—	25·6	Not clear whether mortality from all abdominal wounds, laparotomy only or whether thoracoabdominal wounds are also included (ICRC hospital providing definitive care)
Rozin and Kleinman[15]	1987	Arab–Israeli	40000	178	7·9	All those with abdominal wounds operated on
				141	5·0	Operated on in rear hospital
				37	19	Operated on in evacuation hospital
Fosse *et al*[16]	1988	Lebanon	1500	24	5	Patients transferred within 7 days
Feliciano *et al.*[17]	1988	USA	—	300	11·7	Civilian series, mostly hand-guns; operated on
				226	2·7	With no intra-abdominal vascular injury
				74	39	With intra-abdominal vascular injury
Dumurgier and Jancovici[18]	1989	Chad	—	505	29·0	All laparotomies. Long evacuation to hospital. No blood transfusion possible
Nassoura *et al.*[19]	1991	Lebanon	30000	1314(?)	9·5	Mortality rate from laparotomy '9·5 per cent gunshot wounds' (of 1314 or 706, not clear in text)
				—	2·8	Patients with systolic blood pressure greater than 90 mmHg
				—	26·5	Patients with systolic blood pressure less than 90 mmHg
				—	4·4	With abdominal injury only
				—	14·4	Combined with extra-abdominal injury
Morris and Sugrue[2]	1991	Afghanistan	650	70	13	All patients having laparotomy (ICRC hospital providing definitive care)
Rignault[20]	1992 (quoting)	World War I	—	—	53	Total mortality from abdominal wounds
		World War II	—	—	18–36	Total mortality from abdominal wounds
		Vietnam	6000	476	37·2	Total mortality from abdominal wounds
				338	11·5	Hospital mortality with abdominal wounds (13·5 per cent including negative laparotomy)
				265	9·4	Hospital mortality with primary abdominal wound
				73	19	Hospital mortality from multiple wounds including abdomen
Cuk *et al*[21]	1994	Former Yugoslavia	4292	156	4·5	Primary management in base hospital
				254	14·9	Primary management elsewhere and then transfer to base hospital

ICRC, International Committee of the Red Cross

findings[8,9,12]. The extent of tissue damage along the abdominal track of the missile is important[2,9,10,13,15,18,20], but this has been neither quantified nor interpreted in terms of energy transfer from missile to abdominal organs. However, surgeons do recognize the surgical implications in terms of greater tissue damage in wounds of the liver and colon[2,8,9,18,24–35]. The extent of damage to different organs has been quantified in penetrating abdominal trauma in a civilian setting, but this has been linked only to subsequent complications and not to mortality[36].

The review permits recognition of the elements of severe penetrating abdominal trauma in war. However, the factors responsible for mortality have not been quantified.

Data from the ICRC wound database

The ICRC wound database carries basic information on 25189 war-wounded persons admitted to ICRC hospitals in five different locations; 7479 had wounds scored by the Red Cross wound classification. This classification is a system whereby any wound from any weapon is categorized according to the extent of tissue damage and the structures injured. It is designed as a quick and simple means of gathering data from the field[37–43]. Each wound is given a score according to the size of the skin wound(s), the presence of a cavity in the wound (for abdominal wounds this is indicated by whether the wound in the abdominal wall admits two fingers), whether there is a fracture, whether there has been 'vital injury' (for abdominal wounds this is indicated by breach of the peritoneum or organ injury) and whether there are metallic bodies on radiography. From the score, the wound may be graded according to size (grade 1, small penetrating wounds; grade 2, wounds with a cavity but skin wounds measuring less than 10 cm; grade 3, wounds with a cavity and skin wounds measuring 10 cm or more) and typed according to structures injured (type ST, soft tissue only; type F, fracture; type V, vital injury; type VF, vital injury and fracture). Thus any wound falls into one of the 12 categories shown in *Table 2*.

There is a total of 1148 persons with abdominal wounds and 617 with wounds of the buttocks or pelvis; those with multiple regions wounded are included. Of these, 335 had only abdominal wounds and 195 had only pelvic wounds; those with multiple regions wounded are excluded in the following analysis. *Table 2* shows the different categories into which the isolated wounds of these 530 persons fall, along with the number who died with each category of wound. Of the 530 wounds, 257 (48·5 per cent) did not have a V component, i.e. there was neither peritoneal perforation nor organ injury. Among the 167 people with grade 1 wounds with a V component there were 11 deaths (6·6 per cent mortality rate); among the 106 with grade 2 and 3 wounds with a V component there were 15 deaths (14·2 per cent mortality rate). This difference is statistically significant ($\chi^2 = 4{\cdot}31$, $P < 0{\cdot}05$). The absence of mortality in the 11 who had a grade 3 wound with a V component is explained by the fact that those with such large skin wounds of the abdominal wall survived only because the track of the missile was tangential and therefore did not deliver much of its energy to the abdominal contents. Most casualties with grade 3 abdominal wounds and in whom the track of the missile(s) involved the abdominal cavity die before reaching hospital.

The literature review combined with these ICRC data shows that mortality is related to the number of organs injured, extent of organ injury, blood loss (as indicated by hypovolaemia) and energy transfer from the missile to the tissues (as indicated by the size of the wound in the abdominal wall). How these interplay in the face of variable standards of treatment remains unclear.

Table 2 Categorization by the Red Cross wound classification of wounds in 530 patients who had only one regional wound recorded of either the abdomen or pelvis

Type	Grade 1	Grade 2	Grade 3
ST	126	87	4
F	15	21	4
V	143 (10)	64 (10)	5
VF	24 (1)	31 (5)	6

Numbers in parentheses are those who died; figures are from the International Committee of the Red Cross database. Grade 1, skin wounds less than 10 cm without cavity; grade 2, skin wounds less than 10 cm with cavity; grade 3, skin wounds 10 cm or more with cavity; type ST, soft tissue wound only; type F, wound with fracture, type V, wound with vital injury; type VF, wound with vital injury and fracture

Ballistic analysis

Larger wounds are caused by greater energy transfer from missile to tissue. The two clinical pictures of abdominal wounds seen in the field and their different associated mortality can be explained in these terms. Low energy transfer (LET) results in a narrow wound track and the gravity of the injury is determined by the structures lacerated along this track. As energy transfer increases, the wound track becomes larger and there is a greater chance of peritoneal perforation, multiple organ injury, severe organ injury and major vessel injury; the chance of these components of severe injury occurring in combination also increases. The place of temporary cavitation and shock waves in abdominal wounds has not been established. The transition from LET wounds to the clinical picture of the severe high energy transfer (HET) wounds occurs with a small rise in energy transfer at a critical but undetermined point. However, energy transfer alone does not determine eventual death; the difficulty and urgency of treating HET wounds of the abdomen are additional factors. It seems likely that there exists an exponential component in the relationship between energy transfer to abdominal organs and death rate in treated patients.

Curve A in *Fig. 4* represents mortality with optimal surgical care plotted against transfer of energy within the abdomen. This is arrived at by considering the exponential relationship between death rate and transfer of energy, as outlined above, with two other factors. First, a series of handgun bullets (500 J)[44] gives an overall mortality rate of around 12 per cent in a good surgical facility with rapid access to the patients. Second, even with optimal treatment, few people would survive the transfer of all the energy of an assault rifle bullet within the abdominal cavity or the retroperitoneal structures. Such a bullet imparts between 2000 and 3000 J and the resulting track of permanent damage, if 20 cm long, is about 15 cm in diameter[44]; the extent of tissue damage is most likely irreparable, even if the surgeon succeeds in arresting the haemorrhage. This ballistic analysis is supported in part by the rapidly increasing mortality rate associated with increasing number of organs injured, as reported by Nance *et al.*[6] The shape and position of this hypothetical

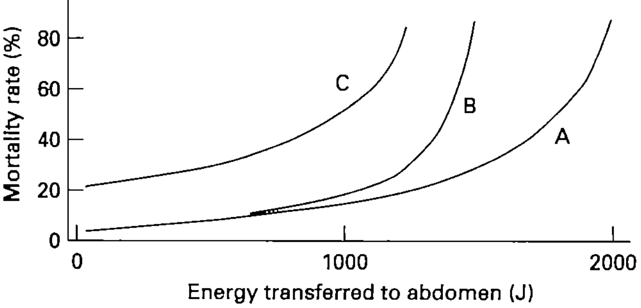

Fig. 4 A hypothetical graph showing energy transfer from missile to abdominal organs plotted against mortality rate for patients with abdominal wounds The significance of curves A, B and C is explained in the text

curve A could be debated; its importance lies in explaining how a linear increase in energy transfer generates two dissimilar clinical groups. Any factors that influence overall mortality from abdominal wounds may be referred to this curve. (If accurate data were ever made available, it is possible that curve A would prove to be part of a sigmoid curve.)

The literature review indicates that the mortality rate associated with LET wounds is about 10 per cent if competent treatment is available. A working value of 50 per cent for the mortality rate from HET wounds with optimal treatment is reasonable if close-range shotgun wounds are considered as equivalent[4,45]. The proportion of people with abdominal wounds who need front-line surgery[15], the proportion of handgun bullet wounds that affect major abdominal vessels[17] and the proportion of abdominal wounds that are grade 2 or 3 with a V component as given by the Red Cross wound classification (*Table 2*) suggest that patients with HET wounds are in the minority. For the purposes of this paper this proportion will be taken as 20 per cent; obviously this will change with each minute added to the time taken to reach hospital.

Constraints imposed by war on optimal management of abdominal wounds

The ballistic analysis permits quantification of the impact on mortality of constraints such as a delay before surgery, insufficient resource or lack of surgical and anaesthetic competence. A competent surgical facility with adequate resource and early access to the wounded, which can provide optimal care, would generate curve A in *Fig. 4*. This should represent the objective of modern military surgical care. However, if the wounded receive competent treatment but after a delay of hours, the 20 per cent with severe wounds die before reaching surgical treatment; this is represented by curve B and would be generated in the context of an ICRC hospital with more difficult access to the wounded and fewer resources. However, if the hospital is undersupplied, overwhelmed and the medical personnel are tired, untrained or frightened, neither competent surgical care nor safe anaesthetic practice is likely. Those with HET wounds are lost anyway and, importantly, the mortality rate of the majority with LET wounds rises, as represented by curve C.

If, with treatment available, the mortality rate from HET abdominal wounds is 50 per cent (which is a generous estimate), total lives lost in the different situations can be calculated. In the situation represented by curve A, for every 100 patients with abdominal wounds, ten lives are saved in those with HET wounds in addition to the 72 (90 per cent) of the 80 lives saved in those with simple wounds. In the situation represented by curve B, only the 72 lives of those with LET wounds would be saved; those with HET wounds would die before reaching hospital. Paradoxically, hospital mortality is lower in the situation represented by curve B. If the constraints also cause the mortality rate of those with LET wounds to rise from 10 to 20 per cent, as represented by curve C, by the same calculation only 64 lives per 100 would be saved. This model demonstrates that those with LET abdominal wounds must not be denied competent surgical care by focusing all surgical time, energy and resource on those with HET wounds. A relatively small rise in the mortality rate of the majority with LET wounds outweighs any spectacular successes within the minority with HET wounds. If curve A is obviously not achievable, the mortality rate associated with curve B should be accepted. Disagreement with the above figures based on different estimates is certain; it should be considered as a first attempt to rationalize a complex subject. Whatever else, the existence of a recognizable minority with HET wounds with specific clinical and logistic implications cannot be denied.

A selective conservative approach to abdominal wounds, requiring refined judgement[6,7], has not been evaluated in war and is unlikely to be. But approximately one-quarter of patients with handgun bullet wounds would survive without laparotomy[6,7,46], and nearly half of the war wounds of the abdominal region neither penetrate the peritoneal cavity nor cause serious injury, as shown in *Table 2*. Anecdotally, some patients with intestinal perforation from war wounds survive without surgery[1,8]. Therefore, as represented by curve C, an increased mortality rate associated with laparotomy for LET wounds under front-line conditions has serious implications, because of the significant proportion of people who do not need to be exposed to that risk for their survival. Surgical judgement is required to identify not only those who need urgent operation but also those who do not need laparotomy at all; this judgement may not be available in the chaos of the front-line hospital.

Other constraints have been reported that are referrable to this model. Two military authors acknowledge that providing rapid first aid and evacuation to a surgical hospital is difficult, if not impossible, when the force concerned is in retreat[47,48]. Transporting the wounded after laparotomy is associated with a high mortality rate[8,15,21,22,49]. This may represent a combination of operations performed under front-line conditions for more severe injury, transport in the early postoperative period, disruption of immediate postoperative care, or a combination of these. Potent influences on surgical judgement and competence are human constraints such as training, food, sleep and security[8,15,25]. Only two papers, both of which report a low mortality rate, refer to the seniority of the front-line surgeons[14,15]. Blood for transfusion is a particularly important resource for treating HET abdominal wounds; this is usually unlimited in a military situation and may be so in a non-military situation[19,50]. In other situations the volume of safe blood may be limited[2,5,18]. Whatever the constraint, those with HET wounds are the most susceptible; by accepting the mortality rate associated with curve B, that associated with curve C can be avoided.

Colonic wounds: the debate

Ogilvie[8] is frequently quoted as proving that death from colonic wounds was reduced as a result of mandatory colostomy. Although he strongly recommended colostomy for all colonic wounds, the small colonic wounds in his series that were closed primarily were associated with a lower mortality rate than others. Many authors have since recommended primary closure of small wounds. Exteriorization, resection or repair with colostomy has been reserved for larger wounds with faecal soiling and/or injury to other organs, especially when the general condition of the patient is poor[2,25-28]. This policy is supported by data from civilian practice[29-33]. Two reports support primary closure or anastomosis without selection of those with smaller wounds[51,52]. There are no mortality figures that support mandatory colostomy for all wounds of the colon. Surgeons should not get caught in the trap of categorizing wounds by weapon or presumed velocity of the missile[34,35,53]. In addition, the need for a second operation to close the colostomy is a significant factor, especially in a developing country at war where this may not be done safely. These arguments do not apply to the protection of repaired rectal wounds with a proximal colostomy; all authors agree on this.

The ballistic analysis of abdominal wounds applies here also. LET wounds affecting the colon are unlikely to be associated with extensive intra-abdominal damage and hypovolaemia, and so the simpler and safer surgical option may be to repair such wounds. By contrast, the simpler and safer operation for colonic injury associated with HET may be to resect the damaged colon and bring out a colostomy or to exteriorize the injury. In HET wounds, some of the viable intestine remaining might nevertheless have the integrity of its 'gut barrier' breached; in combination with haemorrhagic shock, this has implications for the absorption of endotoxins and later multiple organ failure[54]. In the face of the several factors related to energy transfer, it is unlikely that mortality is affected by the choice of operation, assuming a proper level of judgement, experience and competence.

Conclusions and recommendations

Assuming competent surgical care, energy transfer from the missile to tissue is the most important factor determining the mortality associated with abdominal wounds in war. Those with HET wounds of the abdomen are identifiable before operation by the likely direction of the missile track, the size of the wound in the abdominal wall and low systolic blood pressure on admission. They require greater urgency, judgement, expertise and resources, and inevitably have a high mortality rate. Their successful treatment is easily made impossible by the constraints imposed by war.

A well organized military medical service should ensure that those wounded with a genuine need for urgent laparotomy because of bleeding and who would die within hours can, first, have immediate access to a competent and fully supported surgical facility and, second, be evacuated safely[15]. A 'damage control' philosophy[55] may apply to the minority of wounded and presumes that the patient will reach more competent care later. The majority with LET wounds and without signs of bleeding should be given intravenous fluids, antibiotics and analgesia; they will tolerate the transport to a more secure and competent surgical environment. Outside a conventional military context, the focus of surgical resource and competence should always be on the majority with intestinal perforation only, who need surgery to save life but not necessarily on an urgent basis and who have a good chance of survival. The desire to provide urgent surgery must not preclude competent surgical care. Whatever the circumstances, inexperienced and under-equipped surgeons should not attempt the most difficult surgical tasks under the most difficult conditions.

The reality of modern wars must be acknowledged: civilian casualties predominate. Military forces are likely to be used in a United Nations context and the wounded cannot travel along a conventional chain of evacuation. Military doctors may have difficulty accepting that optimal care may not reach the minority with severe wounds[56]. This approach also questions the value of telesurgery for the war wounded, which is often portrayed as laparoscopic surgery performed by robots[57]. To make the claim that deployment of this technology at the front line saves the lives of soldiers with abdominal wounds requires that it be shown to work successfully in the minority with HET wounds, for whom the judgement and operative expertise required are far beyond those needed for performing intestinal repair or resection and anastomosis.

A surgeon receiving wounded who have had a front-line laparotomy where the level of surgical competence or ethics is in doubt should seriously consider a routine 'second-look' laparotomy. This may prevent death for those who have been subjected to an incompetent laparotomy and who have not yet become seriously ill through prolonged sepsis. This does not help with the management of patients who arrive already septic and with evident intestinal leakage after front-line surgery. This review may help avoid this situation.

Laparoscopic ultrasonography during cholecystectomy

M. A. RÖTHLIN, O. SCHOB, R. SCHLUMPF and F. LARGIADÈR

Department of Surgery, Zürich University Hospital, Ramistrasse 100, 8091 Zurich, Switzerland
Correspondence to: PD Dr M. A. Röthlin

The routine use of intraoperative cholangiography during cholecystectomy has been debated extensively. Intraoperative ultrasonography was a quick, efficient alternative in open cholecystectomy. A prospective controlled trial to evaluate its usefulness in laparoscopic cholecystectomy is reported. Two groups of 100 patients each were examined during operation with laparoscopic ultrasonography and intraoperative cholangiography. In the first group an adapted urethral probe was used and in the second group a new specialized laparoscopic probe. Intraoperative cholangiography followed immediately after laparoscopic ultrasonography in each patient. In group 1 bile duct stones ($n = 4$) were detected with a sensitivity of 100 and 75 per cent, a specificity of 98 and 99 per cent, and an overall accuracy of 98 per cent for both ultrasonography and cholangiography. In group 2, 11 patients demonstrated common duct calculi. The sensitivity, specificity and overall accuracy for laparoscopic ultrasonography and intraoperative cholangiography were 91 and 64 per cent, 100 and 100 per cent, and 99 and 96 per cent respectively. The differences between groups 1 and 2 and between ultrasonography and cholangiography were not significant. Variations in the anatomy of the bile duct were observed in 21 patients in group 1 by laparoscopic ultrasonography and in 20 by intraoperative cholangiography. In group 2, 64 variations were demonstrated in 50 individuals by ultrasonography and 61 variations in 47 patients by cholangiography. Vascular variations were seen with ultrasonography in 22 and 24 patients in groups 1 and 2 respectively. In conclusion, laparoscopic ultrasonography (with either probe) proved as accurate as intraoperative cholangiography in detecting bile duct stones, and the specialized probe detected significantly more variations of the bile duct than the adapted probe.

The value of intraoperative cholangiography has been debated for years[1,2]. The introduction of laparoscopic cholecystectomy resulted in a short lull in the debate, which was soon recommenced with renewed vigour[1–5].

In the 1980s a few trials were held to test intraoperative ultrasonography against intraoperative cholangiography in open cholecystectomy[6–8]. The results of both techniques were similar, but intraoperative ultrasonography was never widely used in this context. The main issue at open cholecystectomy was the detection of common duct stones, whereas visualization of anatomical variations of both bile ducts and hepatic vessels was of greater importance after the change to the laparoscopic approach[4,5].

To evaluate intraoperative laparoscopic ultrasonography and intraoperative cholangiography in the detection of common duct stones and anatomical variations, a prospective controlled study employing both techniques was conducted. At the beginning of the study only an adapted probe was available. A specialized laparoscopic scanner subsequently became available. These scanners are costly and the study aimed to determine whether or not the improved results of a laparoscopic ultrasonography probe justify the additional expense.

Patients and methods

Between 1 January 1992 and 31 January 1993, 100 successive unselected patients undergoing laparoscopic cholecystectomy were entered into group 1 of the study. Five additional patients underwent conversion to open cholecystectomy for bleeding ($n = 3$) or inability of the surgeon to delineate anatomical structures ($n = 2$). Group 2 consisted of 100 patients who underwent laparoscopic cholecystectomy between 1 April 1994 and 30 November 1995. During this time, conversion to open cholecystectomy was necessary in three additional patients for bleeding. Sex, age and indication for the operation in the two groups are given in *Table 1*.

Patients in group 1 were examined with a 5·5-MHz sector scanner with a 360° angle and a mobile ultrasound unit (type 3535; B&K Medical, Nærum, Denmark). The probe (type 1850/8523; B&K Medical) had originally been designed for endoluminal ultrasonography of the urinary tract. Its rigid shaft measured 31 cm in length and 7 mm in diameter. The scanner's optimal working depth lay between 1 and 4 cm and it produced 3·5 pictures per second. A protective tube with a plastic tip (type WA 500; B&K Medical) and an outer diameter of 9·5 mm was constructed to protect the tissue from the rotating probe.

Later a probe specially developed for laparoscopic ultrasonography (type 8555; B&K Medical, Gentofte, Denmark) was employed for group 2. The probe consisted of a curved array scanner with a frequency of 5–7·5 MHz mounted on a rod 43 cm in length and 9·5 mm in diameter. The tip of the scanner could be deflected 90° up and down. In contrast to the adapted probe it was capable of both real-time imaging and colour flow Doppler scanning. Both scanners can be immersed in Gigasept (Schülke and Hays GmbH, Zurich, Switzerland) for sterilization.

Preoperative investigation included the patient's history, physical examination and laboratory tests (haematological data, bilirubin, amylase, aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase) as well as abdominal ultrasonography

Paper accepted 28 June 1996

Throughout the study laparoscopic ultrasonography was performed by one surgeon (M.A.R.) exclusively. He had had 14 years' experience with emergency, open intraoperative and interventional ultrasonography. His experience in laparoscopic sonography before the beginning of the study was limited to about 30 cases.

Laparoscopic ultrasonography was performed after dissection of the cystic duct and artery in all patients The technique of the examination and normal anatomy have been described in detail elsewhere[9,10] Briefly, the subhepatic space was flooded with saline solution until the hepatoduodenal ligament had been well covered. The scanner was then introduced through a 10-mm cannula in a left paramedian position. The tip was placed in the hepatic hilum where the examination was started. The shaft of the scanner lay parallel to the ligament and the image showed either a transverse (group 1) or a longitudinal (group 2) section of the structures within the ligament. The scanner was slowly retracted over the ligament as far as the cranial edge of the pancreas where the common bile duct curves to the right. The scanner was then rotated to the right to follow the duct into the head of the pancreas to the papilla of Vater. The probe was then removed, the saline was aspirated and the operation continued. The time taken for laparoscopic ultrasonographic examination was measured from the start of flooding to the removal of the scanner. A diameter of less than 7 mm was considered normal for the common bile duct. A sharp echo with an acoustic shadow, situated in the bile ducts, was considered a positive finding for a bile duct stone. Ultrasonographic findings were recorded immediately after the examination, outside the operating theatre, while intraoperative cholangiography was being performed by the operating surgeon.

A 4-Fr ureteral catheter (Rüsch, Kernen, Germany) was passed through a 14-G intravenous cannula into the abdomen The catheter was inserted into the cystic duct through a lateral incision and fixed with an atraumatic grasper. First 5 ml and then 20 ml of undiluted Urografin (Schering, Berlin, Germany) was injected. Fluoroscopy was performed with a mobile C arm (Siremobil 4E; Siemens, Erlangen, Germany). A diameter of less than 9 mm was considered normal for the common bile duct. A circular filling defect in the bile duct was defined as a positive finding for a bile duct stone. The time taken for intraoperative cholangiography was measured from the incision in the cystic duct to the removal of the C arm Allergy to contrast medium or iodine, as well as pregnancy, were considered contraindications for cholangiography.

Patients in group 1 with suspected common duct stones were subjected to preoperative endoscopic retrograde cholangiopancreatography (ERCP). By the time the second group was examined, however, laparoscopic bile duct exploration was possible and preoperative ERCP was not considered mandatory in patients with suspected stones. Bile duct calculi found during operation were removed either during laparoscopic cholecystectomy (group 2) or by postoperative ERCP (group 1), thus corroborating the intraoperative findings.

Statistical analysis was performed with Statview SE Plus software (Abacus Concepts, Berkeley, California, USA) with the unpaired Student's *t* test, Fisher's exact test or the Mann–Whitney *U* test where applicable.

Results

Laparoscopic ultrasonography was performed successfully in all patients. Intraoperative cholangiography had a success rate of 93 per cent in group 1 and of 90 per cent in group 2 ($P = 0{\cdot}32$). In group 1 cholangiography failed in six patients for technical reasons. In one patient it was not performed because of a history of a severe allergic reaction to contrast medium. In group 2, eight failures of cholangiography were due to technical problems, while two patients had a history of allergic reactions to contrast medium.

Bile duct calculi

Common duct stones were verified during or after operation in four patients in group 1 and in 11 in group 2 ($P = 0{\cdot}02$). Laparoscopic ultrasonography demonstrated all four stones in group 1 and ten of 11 in group 2. Intraoperative cholangiography showed three and seven stones in groups 1 and 2 respectively. In group 1, two false-positive findings occurred at laparoscopic ultrasonography. In one patient this was due to debris in a juxtapapillary diverticulum and in the other a stone seen with both techniques could not be verified at ERCP 2 days after operation and was, therefore, counted as false positive. No false-positive findings occurred in group 2 for either technique. The sensitivity, specificity and overall accuracy resulting from these findings are shown in *Table 2*.

The diameter of the stones ranged from 2 to 7 (mean(s.d.) 3·3(1·6)) mm in group 1 and from 1 to 20 (mean(s.d.) 4·9(4·5)) mm in group 2. In group 1 bile duct dilatation was observed in two of three patients by cholangiography and in all four patients with common duct stones by ultrasonography. Five of seven patients with common duct stones demonstrated by intraoperative cholangiography in group 2 had dilated ducts. In seven of ten patients with a positive finding at laparoscopic ultrasonography the bile ducts were dilated.

Anatomical variation of the bile duct

Variations of the biliary anatomy were demonstrated by laparoscopic ultrasonography in 21 patients in group 1. Intraoperative cholangiography showed anatomical variations in 20 patients in group 1. All variations of the cystohepatic junction visualized by ultrasonography were corroborated by cholangiography, which detected a further case with a junction on the left side of the common bile duct. One patient had an extrahepatic junction of the hepatic ducts, with the cystic duct joining the right hepatic duct, shown by laparoscopic ultrasonography. This variation was subsequently shown by intraoperative cholangiography to be an aberrant hepatic duct joining the cystic duct. Two further patients demonstrated an extrahepatic junction of the left and right hepatic duct on ultrasonography, while the level of the hepatic junction could not be judged by cholangiography because points of reference were missing. Therefore, additional information was contributed by intraoperative cholangiography in two patients, while laparoscopic ultrasonography provided more information in a further two. The variations demonstrated with the two techniques are listed in *Table 3*.

Table 2 Sensitivity, specificity and accuracy of laparoscopic ultrasonography and intraoperative cholangiography in the detection of common duct stones

	Group 1	Group 2
Laparoscopic ultrasonography		
Sensitivity (%)	100	91
Specificity (%)	98	100
Accuracy (%)	98	99
Intraoperative cholangiography		
Sensitivity (%)	75	64
Specificity (%)	99	100
Accuracy (%)	98	96

Total no. of patients	22	24	0·62

Values in parentheses are additional cases found by dissection during operation. RHA, right hepatic artery; SMA, superior mesenteric artery. *Fisher's exact test.

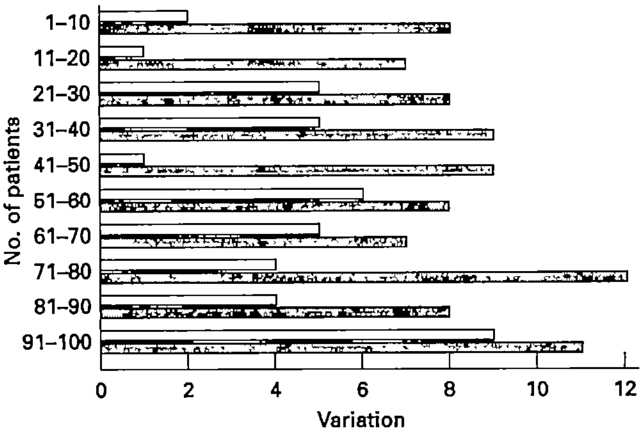

Fig. 1 Learning curve for the detection of anatomical variation: □, group 1; □, group 2

In group 2, 64 anatomical variations of the biliary tree were visualized by laparoscopic ultrasonography in 50 patients Intraoperative cholangiography demonstrated such variations in 61 cases. It provided additional information in three patients (one dorsal junction and two junctions on the left of the hepatic duct). In six patients with an extrahepatic low junction of the hepatic ducts, cholangiography could not corroborate the findings owing to the lack of points of reference. Significantly more anatomical variations of the bile ducts were found in group 2 (*Table 3*). Both dorsal and intrapancreatic cystohepatic junctions were observed significantly more frequently in the second group ($P = 0{\cdot}0001$).

Anatomical variations of the hepatic arteries

Variations of the hepatic arteries were seen in 21 patients in group 1 by laparoscopic ultrasonography only, and in one patient by both ultrasonography and cholangiography (compression of the hepatic duct by a right hepatic artery crossing ventrally). In group 2, 24 cases were detected by laparoscopic ultrasonography. Two additional cases (cystic arteries crossing ventrally) were discovered during further dissection and considered false-negative results. The difference in the number of vascular variations in groups 1 and 2 was not significant ($P = 0{\cdot}62$). The types of variation observed in the two groups are shown in *Table 4*. The number of all anatomical variations detected ultrasonographically in relation to the experience of the observer (learning curve) is demonstrated in *Fig. 1*.

Time required for examination

The time necessary for the laparoscopic ultrasonographic examination in group 1 ranged from 2 to 12 (mean(s.d.) 5·4(2·4)) min. Intraoperative cholangiography was performed in 4–37 (mean(s.d.) 16·4(7·4)) min. The difference was highly significant ($P = 0{\cdot}0001$). In group 2 the time range for laparoscopic ultrasonography was 2–10 (mean(s.d.) 4·5(1·7)) min, while for intraoperative cholangiography it was 7–30 (mean(s.d.) 13·5(4·5)) min. Again, the difference was highly significant ($P = 0{\cdot}0001$).

Discussion

During conventional cholecystectomy intraoperative ultrasonography has been used by only a few groups[6–8]. The results of intraoperative ultrasonography were similar or even better than those for intraoperative cholangiography. The sensitivity and specificity for the detection of bile duct stones ranged from 93 to 96 per cent for intraoperative ultrasonography and from 93 to 99 per cent for intraoperative cholangiography. At the beginning of laparoscopic cholecystectomy, routine intraoperative cholangiography was recommended by some to avoid bile duct injury[4,5]. In 1991 the present authors started evaluating laparoscopic ultrasonography as an alternative to intraoperative cholangiography. At the time there were no laparoscopic ultrasonographic probes available and an adapted probe was used for the first group of patients. At the same time a dedicated probe for laparoscopic ultrasonography was developed in collaboration with B&K Medical in Denmark. This new scanner was employed for the second group of patients. In the meantime other authors have demonstrated several advantages to the routine use of laparoscopic ultrasonography[11–14].

Both the sensitivity and specificity attained with laparoscopic ultrasonography in the authors' and other groups' experience[11–14] are similar to those reported for conventional intraoperative ultrasonography[6–8]. In this study laparoscopic ultrasonography visualized small bile duct calculi and sludge invisible on intraoperative cholangiography in five cases. Lane and Coupland[6] have already described this phenomenon with conventional intraoperative ultrasonography. These findings are even more significant because in both studies the ultrasonographic findings were known at the time intraoperative cholangiography was performed. In group 1 only a small number of unsuspected bile duct calculi was detected during operation. This small number explains the large difference in sensitivity between laparoscopic ultrasonography and intraoperative cholangiography. The overall accuracy rate of 98 per cent for both methods demonstrates their value more clearly.

In the second group both suspected and unsuspected common duct stones were treated laparoscopically, hence the significantly ($P = 0{\cdot}02$) higher number of common duct stones in the second group. Two of the four false-negative cholangiography findings in group 2 concerned patients in whom cholangiography had failed for technical reasons. One of these patients had Mirizzi syndrome. There were two false-positive findings for bile duct stones on laparoscopic ultrasonography in group 1. The first patient also had a positive cholangiographic examination. This was a patient in whom the stone could not be demonstrated by ERCP 2 days after operation. Bile duct calculi that cause acute pancreatitis are known to pass into the duodenum within 10 days in 84–95 per cent of cases[15,16]. In addition, the discrepancy between the number of bile duct stones found by routine intraoperative cholangiography and the incidence of sympatomatic stones left behind at cholecystectomy without cholangiography suggests that only one stone in 20 produces symptoms[17]. There is a possibility, therefore, that both the intraoperative modalities used did in fact show a true stone that had passed before ERCP was performed. The second patient was found to have a juxtapapillary diverticulum on intraoperative cholangiography, and the ultrasonographic findings were attributed to debris in this diverticulum rather than to a stone invisible on cholangiography. Laparoscopic ultrasonography with either of these scanners is at least as accurate as intraoperative cholangiography in finding bile duct calculi, and there is no difference between the adapted and dedicated scanners in this context.

In the beginning the reasons for routine performance of intraoperative cholangiography during laparoscopic cholecystectomy differed slightly from those in conventional cholecystectomy. More emphasis was placed on visualization of biliary anatomy, while the detection of common duct stones was considered of lesser importance[3,4]. The incidence of bile duct injury occurring during laparoscopic cholecystectomy may reach 1 per cent or more[18]. Routine intraoperative cholangiography is supposed both to diminish the number of bile duct injuries[5,19] and to increase the number of iatrogenic injuries detected immediately. While only the extrahepatic bile ducts can be scanned with the equipment used for laparoscopic ultrasonography in group 1, intraoperative cholangiography and the scanner used for group 2 are capable of showing the entire biliary tree. Intraoperative cholangiography had to be aborted for technical reasons in seven patients in group 1 and in ten in group 2, while laparoscopic ultrasonography was completed successfully in all patients. The Southern Surgeons Club, in fact, published a failure rate of 23 per cent for laparoscopic intraoperative cholangiography in 1991[20]. Laparoscopic ultrasonography has an additional advantage over intraoperative cholangiography in that it can be performed at any time during the operation, even before dissection has taken place. Laparoscopic ultrasonography detected variations of the biliary anatomy in 21 cases and intraoperative cholangiography in 20 cases in group 1. Twenty-two arterial anomalies were found by laparoscopic ultrasonography in the same group of patients. In group 2 the number of arterial variations ($n = 24$) was similar to that in the first group, whereas the number of biliary variations ($n = 50$) was significantly higher ($P = 0{\cdot}001$). A total of 65 patients were found to have a variation of either the arterial or biliary anatomy. This corresponds well with several anatomical studies on cadavers[21–23] that revealed anatomical variation in up to 65 per cent of cases These data indicate that in group 2 most anatomical variations present were demonstrated ultrasonographically. The only exception to this was the cystic artery, which is visible regularly only if colour flow Doppler scanning is used routinely. The distinction between the effect of the new probe and the increasing experience of the observer on the detection rate for anatomical variation is difficult to make. After the first 20 patients studied, the learning curve (*Fig. 1*) showed a constant rate of about five variations per ten patients in group 1. The rate in group 2 was similarly constant at about nine variations per ten patients. These findings suggest an improvement of the detection rate as a result of the new probe. The main difference between groups 1 and 2 with respect to the number of biliary variations at laparoscopic ultrasonography was found to be the number of dorsal cystohepatic junctions (seven *versus* 29 patients, $P = 0{\cdot}0001$) and the number of intrapancreatic junctions (six *versus* 17 patients, $P = 0{\cdot}0001$). As the two variations are often associated, this finding suggests that the dedicated ultrasonographic scanner permits better visualization of the pancreatic head.

Laparoscopic ultrasonography has the advantage of showing bile ducts and blood vessels, whereas intraoperative cholangiography demonstrates only the biliary tree. Cholangiography revealed a similar number of biliary anatomical variations to the number found with ultrasonography. The fact that the number of variations demonstrated by intraoperative cholangiography equalled those seen ultrasonographically can, at least to some extent, be explained by the surgeon's knowledge of the ultrasonographic findings at the time of performing intraoperative cholangiography. Another reason for the increase in anatomical variation found by cholangiography is the experience of the surgeons gained by routine application of the technique over 3 years.

Many surgeons refrain from using intraoperative cholangiography routinely because of the time necessary for the examination. The time taken for conventional intraoperative cholangiography is reported to be between 23 and 27 min[1,24] and the introduction of the laparoscopic technique has not reduced this[25,26]. In fact, the mean times of 16·4 and 13·5 min reported in the present study are the lowest published in a prospective trial so far. Both conventional intraoperative ultrasonography and laparoscopic ultrasonography with either scanner were significantly ($P = 0{\cdot}0001$) faster to perform[6,8,14], the mean time required was between 4 and 6 min

In conclusion, laparoscopic ultrasonography proved at least as accurate as intraoperative cholangiography in the detection of common duct stones. The detection of anatomical variations is improved by the dedicated scanner, although the surgeon's growing experience with the technique might have played a role as well. While considerable ultrasonographic experience was required for laparoscopic ultrasonography to be performed successfully with the adapted scanner, the specialized scanner capable of real-time imaging and colour flow Doppler scanning facilitates the use of laparoscopic ultrasonography for surgeons with little ultrasonographic experience. The new scanner also permitted better visualization of the pancreatic head and liver. The authors consider laparoscopic ultrasonography a reliable, quick and accurate alternative to intraoperative cholangiography during laparoscopic cholecystectomy.

The aim of this retrospective study was to analyse outcome in 31 European patients operated on for peripheral cholangiocarcinoma between 1988 and 1995 (hilar cholangiocarcinoma was excluded). Before 1992, in addition to conventional resection, patients with irresectable tumour and with no extrahepatic metastasis underwent total hepatectomy with liver transplantation. Mild abdominal pain was the most frequent presenting clinical sign (11 of 31 patients) and jaundice was present in only four patients. Preoperative histological findings were available for 20 patients but the diagnosis was correct in only eight of these. Nineteen patients had curative surgery: 17 underwent conventional resection and two had total hepatectomy with liver transplantation. Major hepatectomy was performed in 12 of 17 cases, extended to the caudate lobe in five, to the bile duct confluence in four and to the retrohepatic vena cava in one. Postoperative mortality and morbidity rates were three and seven of 19 patients respectively, median survival was 15 months, and actuarial 1-, 2- and 5-year survival rates were 67, 40 and 32 per cent respectively. Twelve patients had only exploratory laparotomy because of the presence of extrahepatic metastasis or irresectable tumour. The invasive nature of peripheral cholangiocarcinoma can explain the limited number of resectable cases and the particularly unfavourable prognosis. Total hepatectomy does not provide survival benefit. Conventional surgery remains the only effective treatment, even for patients with advanced stage tumours.

Intrahepatic cholangiocarcinoma is the second most common primary liver cancer after hepatocellular carcinoma. However, it makes up only 10 per cent of primary liver malignancies, which explains the relatively low populations in the published series. The presence of specific aetiological factors such as hepatobiliary parasitosis or intrahepatic lithiasis makes these tumours more common in the Orient[1,2]. In Europe, their incidence is ten times lower[3].

Intrahepatic cholangiocarcinoma can be divided into two groups according to localization[4]: (1) peripheral cholangiocarcinoma which develops from small duct radicals within the liver; and (2) hilar cholangiocarcinoma, which develops from the major hepatic ducts near or at the junction of the right and left hepatic ducts. The two types differ in structure[5,6], symptoms and progressive neoplastic growth, and therefore require specific therapeutic approaches[7,8]. These differences are in part linked to tumour location relative to the major hepatic ducts: hilar tumours cause early obstructive jaundice, often providing an earlier diagnosis. However, the possibly more aggressive feature of peripheral cholangiocarcinoma could explain the higher incidence of intrahepatic and extrahepatic metastases at the time of diagnosis[9,10].

The aim of this retrospective study was to analyse 31 European patients operated on for peripheral cholangiocarcinoma.

Patients and methods

Between August 1988 and May 1995, 405 patients underwent laparotomy for liver tumour (321 malignancies). Some 339 resections were performed, 81 for benign lesions, 117 for primary and 141 for secondary liver cancers. During the same period, 147 total hepatectomies with liver transplantation were performed (23 for malignancy). In all, 177 operations for primary liver cancer were performed (117 resections, 43 exploratory laparotomies and 17 total hepatectomies with liver transplantation). There were 31 consecutive patients operated on for peripheral cholangiocarcinoma (18 per cent of the patients operated on for primary liver cancer): 23 men and eight women of mean age 56 (range 35–76) years. Ultrasonography and computed tomography (CT) were performed in all patients before operation. Angiography and/or magnetic resonance imaging was performed in eight patients before referral but was not used systematically as a preoperative diagnostic tool. Cavography was performed when invasion of the inferior vena cava was suspected. Twenty patients were referred with the histological or cytological results of a percutaneous biopsy of the tumour, but this procedure was not included systematically in preoperative investigations.

Laparotomy was indicated when the tumour was considered to be resectable No palliative resection was performed. In cases of resectable tumours, systematic lymphadenectomy of the porta hepatis was performed Until 1992, total hepatectomy with liver transplantation was carried out in patients with irresectable tumours and with no extrahepatic metastasis, following systematic exploratory laparotomy

Pathological examination was performed on operative liver specimens, or on large biopsies when resection was not possible. All specimens were re-examined for the purposes of the study. The diagnosis of cholangiocarcinoma was supported by gross and histological data. First, all patients had intrahepatic neoplasms; second, no extrahepatic abdominal primary site was detected during preoperative investigation or laparotomy; third, tumours exhibited the common histological features of cholangiocarcinomas. all were adenocarcinomas with small mucinous glandular structures and desmoplastic stromal response. Cases showing both mucinous and bile deposits were defined as combined hepatocholangiocarcinomas. Tumours were classified according to the criteria of the Union Internacional Contra la Cancrum[11].

No patient was lost to follow-up. Survival data were calculated from the date of resection or transplantation until 31 December, 1995 or the date of death. Actuarial patient survival was estimated by the Kaplan–Meier method. Operative mortality, defined as death within 30 days of surgery or during the same hospitalization, was not excluded from survival analysis.

Paper accepted 30 May 1996

Results

The mean time from the onset of symptoms to operation was 4·5 (range 1–19) months. The most frequent presenting clinical sign was mild abdominal pain ($n = 11$). Other signs at first presentation were palpable abdominal mass ($n = 4$), jaundice ($n = 4$), temperature ($n = 3$), pruritus ($n = 1$), weight loss ($n = 1$), phlebitis of the upper limb ($n = 1$) and Budd–Chiari syndrome with ascites. In five of the 31 patients, the tumour was found during a systematic ultrasonographic or biochemical check-up.
